ELAINE LIM BDS (Univ. Medal)

A thesis submitted in partial fulfilment of the requirements for the degree of
Master of Dental Science (Orthodontics)

Discipline of Orthodontics

Faculty of Dentistry

University of Sydney

Australia

2007

Dedication

It was during a difficult time in my life I managed to find strength with the support of my family and close friends. Their kindness and beautiful hearts enabled me to learn to look forward to the future and to smile again. I am extremely grateful to these special and precious people. Thank-you for helping me heal.

The completion of this Thesis and Degree marks this new chapter in my life. I have been blessed with a second chance – I have learnt what it truly means to *live*.

Dad, Mum, Justin and Selina – I would not have made it without you.

Acknowledgments

Sincere gratitude is expressed to all the following:

Professor M Ali Darendeliler, Head of the Discipline of Orthodontics, Faculty of Dentistry, University of Sydney for his supervision, guidance and support through the course of my post-graduate studies.

Associate Professor G Shen, Discipline of Orthodontics, Faculty of Dentistry, University of Sydney for his assistance regarding the development and preparation of this thesis.

Dr M Arora, Senior Lecturer, Population Oral Health Unit, Faculty of Dentistry, University of Sydney for his research advice.

Dr D Belton, Manager, CSIRO Melbourne, School of Physics, University of Melbourne, for his assistance in scanning of the samples using the CSIRO-GEMOC Nuclear Microprobe machine.

Dr P Petocz, Associate Professor, Department of Statistics, Macquarie University for his assistance with the statistical analysis and presentation.

Dr A Jones, Mr R Mair, Mr D Dwarte, Electron Microscopy Unit, University of Sydney, for their advice on the use of the microscope and digital camera systems used in this research project.

Drs T Rex and M Foo, for their role in the laboratory and clinical aspects of this study.

Dr T Turk, Ondokuz Mayis University, Turkey, for his part in the clinical aspect of Thesis Part 2b.

Dr L Ihsheish, for her editorial advice.

Ms A Davis, for her assistance in the preparation of this thesis.

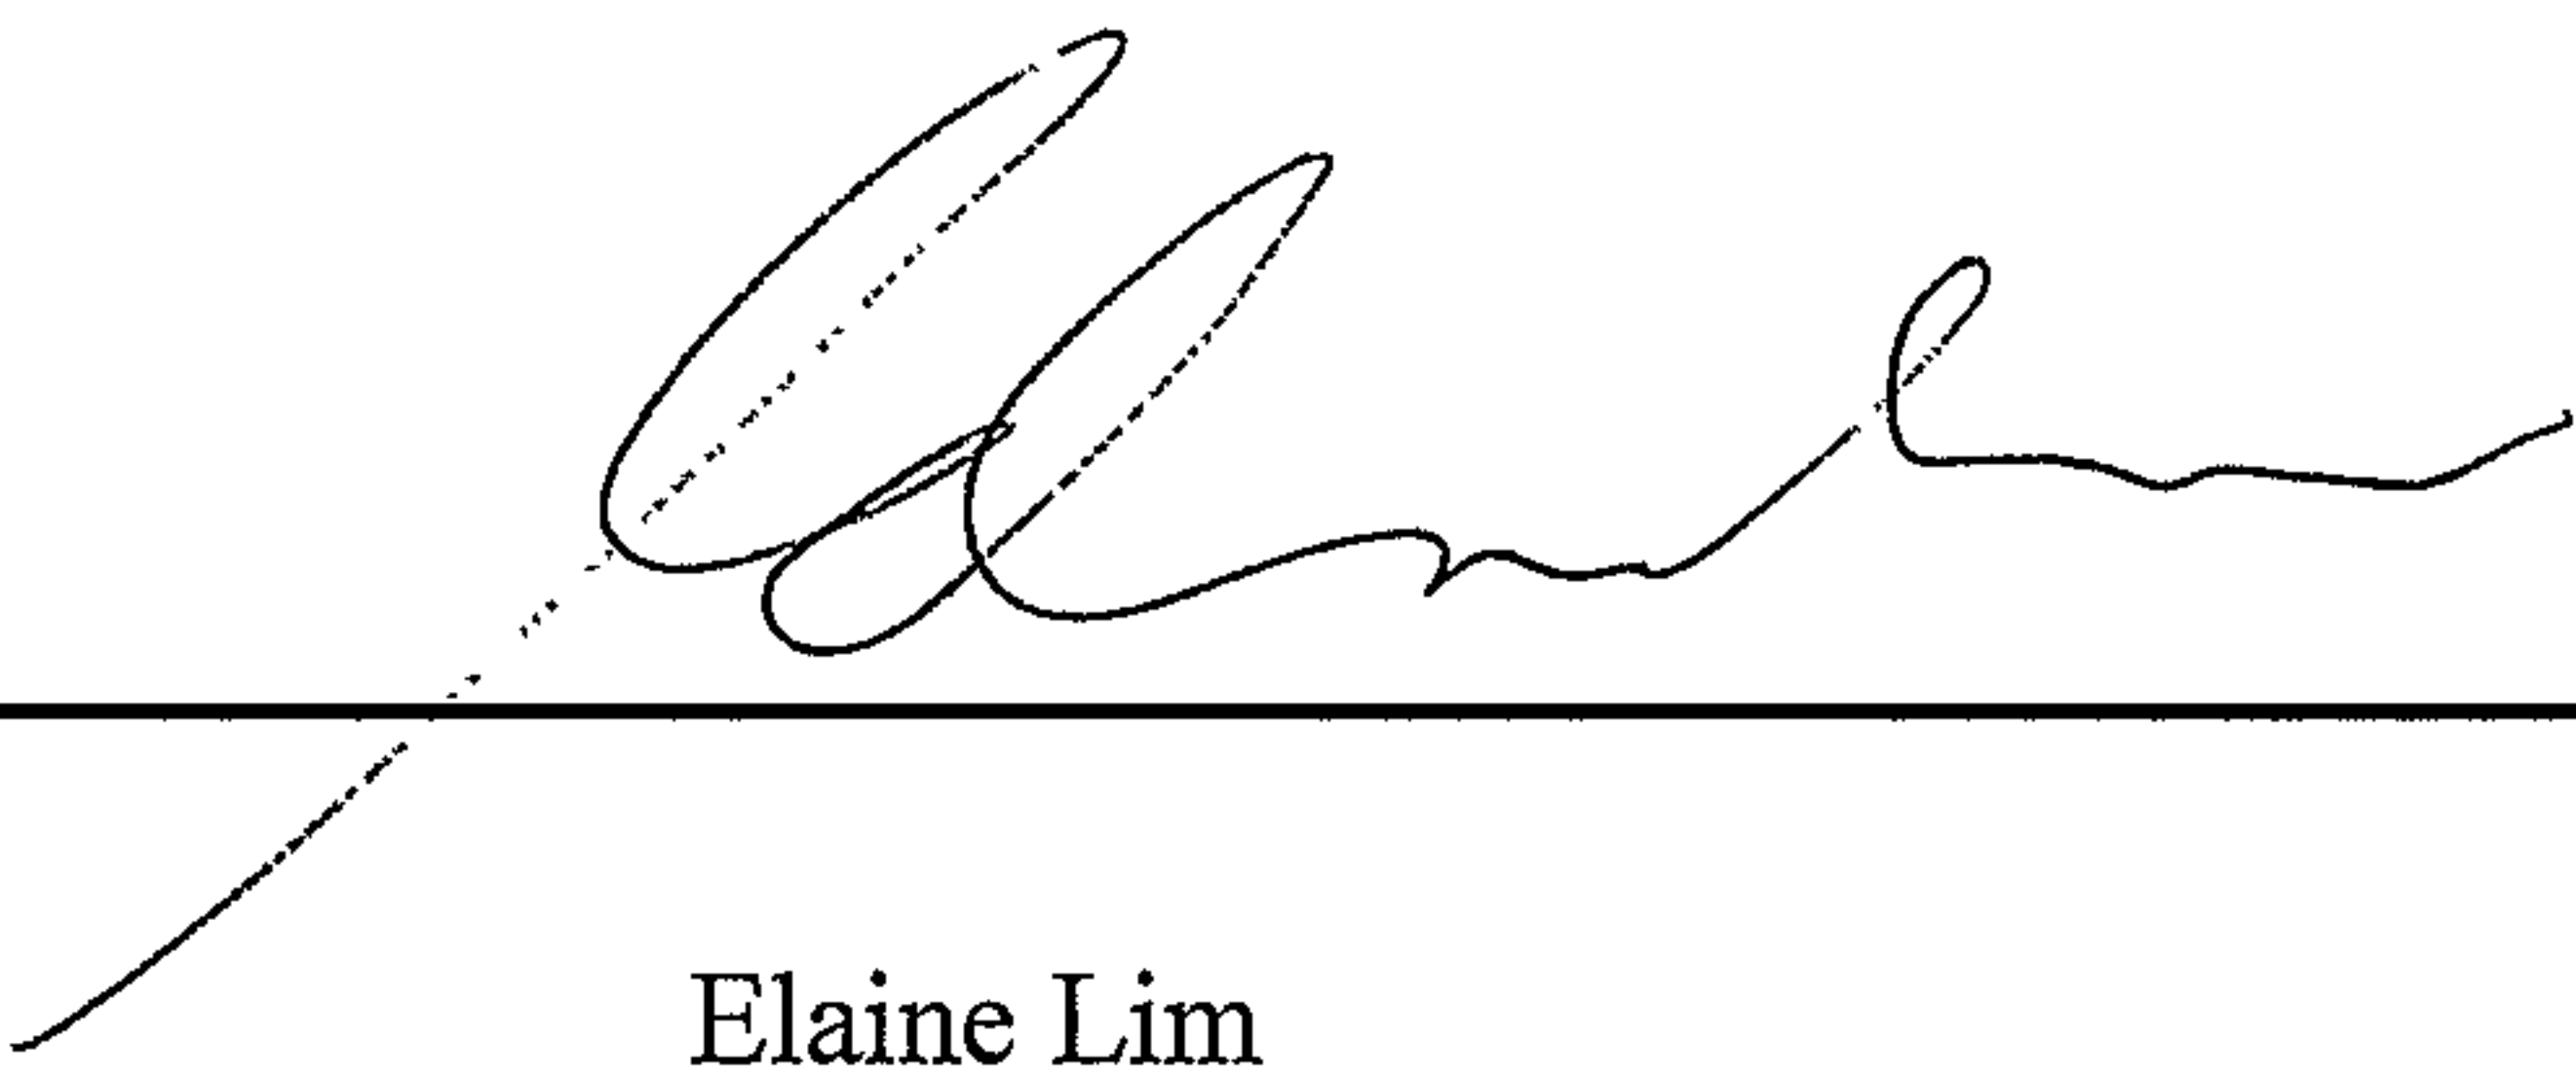

The Australian Society of Orthodontists Foundation for Research and Education, Dental Board of NSW, Dentaurem and AB Orthodontics for their financial support.

My post-graduate colleagues for all the laughter – we made the journey.

Declaration

CANDIDATE CERTIFICATE

This is to certify that the candidate carried out the work in this thesis in the Orthodontic Department, University of Sydney and has not been submitted to any other University or Institution for a higher degree.

Elaine Lim

1. INTRODUCTION

Root resorption refers to loss of tooth structure, which may be physiological (exfoliation of primary teeth) or pathologic (replacement (ankylosis), inflammatory or idiopathic).^{1,2} If the cementum is mechanically damaged, multi-nucleated cells will arrive near the surface and resorption will occur.³ Presence of such cells characterises inflammatory resorption, which may be transient (stimuli present for short duration with minimal damage) or progressive (longer duration).⁴

Root resorption resulting from orthodontic treatment is an unpredictable adverse effect involving transient inflammatory surface resorption. This process has been termed Orthodontically Induced Inflammatory Root Resorption (OIIRR).¹ There are three classifications for the severity of OIIRR: Cemental or Surface Remodelling, Dentinal Resorption With Repair or Deep Resorption and Circumferential Apical Root Resorption.

The mechanism of OIIRR has not been fully elucidated. Following orthodontic force application, tooth movement is associated with a local compression of the periodontal ligament and the development of sterile necrosis.⁵ This morphometric phase is followed by biochemical changes. The sequence of events involves fibre coalescence, hyalinisation, degradation of connective tissue matrices (extracellular and intracellular

pathways)⁶ followed by demineralisation of Sharpey's fibres⁷ and finally odontoclastic activity. The resorptive process initially occurs at the circumference of the necrotic hyalinized area. This is followed by resorption of the root surface in the central part of the necrotic zone.⁸ The later stages also demonstrate areas of peripheral repair.^{9,10}

The prevalence of root resorption in untreated persons ranges from no resorption to 90%.^{11,12} In a ten-year evaluation of the quality of orthodontic treatment, involving 3,300 patients, root resorption between 1-3 mm occurred in all fixed appliances cases.¹³

Associated risk factors for increased incidence of root resorption have been suggested to include: individual susceptibility, genetics, hormonal imbalance, medical history, nutritional balance, age, dental history, tooth type, duration of treatment, amount of tooth movement, appliance type, type of tooth movement and magnitude of orthodontic force.¹⁴

There is currently no consensus on how, or indeed whether, root resorption can be prevented. However, several strategies have been suggested on ways to possibly minimise root resorption. These include: limiting treatment duration,^{15,16} using light intermittent forces,¹⁷ assessment of medical history and familial tendency,^{18,19} control of habits²⁰ and, if required, cessation of treatment.^{21,22}

Unlike bone, cementum has a greater capacity to resist resorption. However, this feature is not yet fully understood. Explanations include: presence of cellular barriers, precementum and the mineral content of cementum.

Cementum is the tooth's dynamic interface to the periodontal environment. Similar to other hard tissues, hydroxyapatite in cementum is not pure, and contains elements from its microenvironment.²³ The minerals in the circulating fluid can react with cementum. In particular, the fluoride ion reacts aggressively with hydroxyapatite.²³ When the root surface is breached, repair matrices become attached to the resorbed surface.²⁴ Following the detachment of odontoclasts the cementogenic cells repopulate. This is followed by electron-dense globular accumulations indicating re-mineralisation.

The opposing hard tissues of cementum and bone have differences chemically, physically and physiologically. Such differences may explain why cementum does not participate in general body metabolism and as a result remains unaffected by many pathologies which affect bone.²³

A study in the veterinary literature appears to be unique in its evaluation of elemental composition of teeth with odontoclastic resorption lesions.²⁵ This study found teeth affected by this pathology had greater concentrations of sodium overall and less iron, whilst in cementum there was a significant

reduction in magnesium and fluorine. No conclusions were made regarding clinical relevance. Although this study provides useful information, it is notable that there was no consideration of elements within the lesions themselves. Furthermore, orthodontic literature has not focused on the effects of altered elements in relation to root resorption.

Literature has been sparse examining the direct relationship of fluoride's potential protective influence and the effect mineral content of cementum may have against orthodontic associated root resorption. Foo et al²⁶ used rats to induce orthodontic root resorption, and exposed part of the sample to systemic fluoride, with an estimated intake of 1 mg per day. It was demonstrated that the average crater volumes of teeth exposed to fluoride were about half the size. However, due to a large variation in results these differences were not significant ($p>0.05$).

Although, fluoride does not increase the physical hardness of cementum *per se*,²⁷ there are a number of possible mechanisms whereby fluoride may impart a protective effect against orthodontically induced root resorption (as opposed to its well described effects on bone resorption). These include: direct effect on osteoclasts, alteration of shapes of resorption pits and the mineralisation of cementum.²⁸ Thus fluoride may be potentially linked to the prevention of OIIRR.

There are various methods to study elemental composition of teeth. Available techniques include microprobe analysis. The nuclear microprobe employs proton induced X-ray emission (PIXE) and proton induced Gamma ray emission (PIGE), which allows mapping of multiple trace elements at micron resolutions. Compared to other available techniques, the Commonwealth Scientific and Industrial Research Organisation-Geochemical Evolution and Metallogeny of Continents Nuclear Microprobe (CSIRO-GEMOC NMP) provides the best trace element spatial and quantitative analysis. However, this technology does not lend itself well to bulk sample analysis. Rather, the data gathered is respected for its high quality.

The aim of this thesis was to develop a methodology using the CSIRO-GEMOC nuclear microprobe machine in order to analyse the elemental composition in tooth root cementum & root resorption craters, and whether they undergo alterations following orthodontic force.

In order to achieve these aims three separate studies were developed which constitute this Thesis:

Part 1: Root resorption craters of rat molar cementum following exposure to systemic fluoride. This study examined the impact fluoride had on the

elemental content of cementum and within orthodontically induced root resorption craters.

Part 2a: Human cementum following heavy and light orthodontic forces. This study explored the effect orthodontic force had on cementum elemental concentration and distribution.

Part 2b: Human root resorption craters. This study aimed to quantitatively and spatially characterise the elemental content of a “typical” OIRR crater.

It is hoped that this Thesis will contribute to our knowledge of orthodontic root resorption and may form a basis from which further research can be conducted in order to help understand and potentially prevent or minimise this treatment side-effect.

2. REVIEW OF THE LITERATURE

2.1 Root resorption

2.1.1 History

Root resorption in secondary teeth was initially described in 1856 by Bates.²⁹ This was later demonstrated radiographically.³⁰

2.1.2 Definition

Root resorption refers to loss of tooth structure, which may be physiological (exfoliation of primary teeth) or pathologic (replacement (ankylosis), inflammatory or idiopathic).^{1,2} Mineralized tissues of the permanent dentition are not normally resorbed.⁴ They are protected in the root canal by dentine and odontoblasts, and on the root surface by cementum and cementoblasts.^{31,32} If the cementum is mechanically damaged, multi-nucleated cells will arrive near the surface and resorption will occur.³ Presence of such cells characterises inflammatory resorption, which may be transient (stimuli present for short duration with minimal damage) or progressive (longer duration).⁴

2.1.3 Classification of root resorption

Three types of external root resorption have been defined: surface resorption (self-limiting process followed by spontaneous repair), inflammatory resorption (root resorption which has reached infected necrotic pulp or infected leukocyte zone) and replacement resorption (replacement by bone leading to ankylosis).³³

An alternative classification of external root resorption has been proposed by Ghafari:³⁴ Inflammatory Resorption (which results from inflammation to a specific stimulus, phagocytic cells and inflammatory mediators eventually affecting dentinal tubules or pulpal tissues), Surface Resorption (transient inflammation confined within the root's more superficial layers, which is usually followed by repair) and Progressive Resorption (with or without bone substitution).

Root resorption associated with orthodontic treatment involves transient inflammatory surface resorption. This process has been termed, Orthodontically Induced Inflammatory Root Resorption (OIIRR).¹

Brezniak and Wasserstein³⁵ describe three classifications for the severity of OIIRR:

1. *Cemental or Surface Remodelling* – superficial resorption followed by repair
2. *Dentinal Resorption With Repair or Deep Resorption* – Cementum and outer dentine are resorbed. Repair with cementum and final root form may differ from the original.
3. *Circumferential Apical Root Resorption* – resorption of root apex resulting in a shortened root.

External surface repair occurs in the cementum only. Therefore, once tooth material is lost beyond the cementum, complete regeneration of the original root morphology is impossible.

2.1.4 Mechanism of root resorption

The mechanism of OIRR has not been fully elucidated, however, fundamentally it has been described in terms of a local inflammatory reaction.³⁶

Mineralised tooth root surface undergoes resorption when odontoclasts gain access via a breach in the formative cell layer,⁴ when precementum is damaged⁴ or when mineral and matrix coincide.⁷

Following orthodontic force application, tooth movement is associated with a local compression of the periodontal ligament and the development of sterile necrosis.⁵ This morphometric phase is followed by biochemical changes. The sequence of events involves fibre coalescence, hyalinisation, degradation of connective tissue matrices (extracellular and intracellular pathways)⁶ followed by demineralisation of Sharpey's fibres⁷ and finally odontoclastic activity.

The resorptive process initially occurs at the circumference of the necrotic hyalinized area. This is followed by resorption of the root surface in the central part of the necrotic zone.⁸ The later stages also demonstrate areas of peripheral repair.^{9,10}

Brudvik and Rygh used rats and mice to demonstrate the cells involved in root resorption.^{8,37} Mono-nucleated, TRAP (tartrate resistant acid phosphatase) negative (non-clast) cells were located at the periphery of the necrotic zone. These resembled macrophages and/or fibroblasts. In the later stages of the resorptive process, multinucleated TRAP-positive giant cells without a ruffled border and mono-nucleated TRAP-positive macrophage-

like cells remove necrotic tissue and surface cementum.⁹ These cells are presumably derived from the mono-nucleated phagocytic system.

2.1.5 Incidence

2.1.5.1 Incidence Untreated Population

Root resorption occurs in untreated as well as orthodontically treated populations. The prevalence of root resorption in untreated persons ranges from no resorption to 90%.^{11,12} Henry and Weinmann¹² found the histological evidence of root resorption craters on 261 permanent human teeth was distributed across the root, with 76.8% of the resorption areas in the apical third, 19.2% in the mid-root region and 4% in the gingival third. There were more resorption craters on the mesial and buccal root surfaces compared with the distal and lingual surfaces. On average the root resorption craters were 0.73 mm in length and 0.10 mm in depth, with the number of craters increasing with age. However, 85% of the resorption areas showed evidence of repair. It was concluded that it is normal for teeth to undergo a certain degree of physiologic resorption, although the morphology of such craters is small, shallow and usually undergo repair.

2.1.5.2 Incidence Treated Population

Root resorption resulting from orthodontic treatment is prevalent and is an unpredictable adverse effect. This creates a potential for damage to teeth and a compromised orthodontic result. In a ten-year evaluation of the quality of orthodontic treatment involving 3,300 patients, root resorption between 1-3 mm occurred in all fixed appliances cases.¹³ After treatment, 41% of adult patients had increased root resorption of over 2.5 mm in one or more teeth,³⁸ whilst an incidence of 93% of treated adolescents has been recorded.³⁹ Other studies, more recently, have demonstrated less root resorption associated with orthodontic treatment. Central incisors suffered an average of 0.77 ± 0.42 mm during treatment and after six month follow-up post-treatment, this had increased to 1.67 ± 0.64 mm.⁴⁰

2.1.6 Risk factors and Aetiology

2.1.6.1 Biologically Related Factors

2.1.6.1.2 Individual susceptibility

Root resorption varies between and within individuals and changes occur over time.²¹ This may be the result of individual susceptibility due to endogenous factors.⁴¹ An increase in the ligand receptor activator of

NFkappaB (RANKL) and a decrease in osteoprotegrin production is evident in those who suffer from severe root resorption.⁴² It is believed that the compression of periodontal ligament (PDL) cells associated with teeth suffering from severe root resorption produce large amounts of RANKL and result in an up-regulation of osteoclastogenesis.

2.1.6.1.3 Genetics

Root resorption may be due to genetic influence as demonstrated in the experience of related individuals.⁴³ One-hundred and three siblings, who had undergone orthodontic treatment, were examined for crown-root lengths on orthopantomographic radiographs and lateral cephalograms. Heritability estimates were high, with the exception of the mandibular incisors. Root resorption may possibly have an autosomal dominant, autosomal recessive or polygenic mode of inheritance.¹⁸ Al-Qawasmi established a link between interleukin genes and external apical root resorption.^{44,45} Samples homozygous for the IL-1B allele 1 had over five times the risk of greater than 2 mm of root resorption, compared to the non-homozygous group. The report describes a genetic marker for this cytokine, which may identify those at risk prior to commencement of orthodontics. Another gene, which may have an effect is TNFRSF11A, which encodes for Tumour Necrosis Factor receptor. This mediates the signalling to osteoclastogenesis.⁴⁶ Thus the genetic contribution has important implications in the pathogenesis and

may explain the variations seen in individuals who experience external root resorption.

Ethnicity may also play a role. In a sample of 868 patients it was found that Caucasian and Hispanic patients experienced less root resorption than those of an Asian background.¹⁴ However, this may need reassessment, as there was a discrepancy in the sizes of the samples used.⁴⁷

2.1.6.1.4 Hormonal imbalance

Hormonal imbalances affect bone metabolism. These have also been linked to root resorption. Three hormones primarily control the metabolism of mineralised tissues – Vitamin D (1,25-Dihydroxycholecalciferol), calcitonin and parathyroid hormone.⁴⁸

Vitamin D undergoes a pathway of hydroxylation to form the steroid hormone 1,25-Dihydroxycholecalciferol, resulting in increased calcium absorption in the kidney. The thyroid gland secretes calcitonin, which is an inhibitor of bone resorption. The parathyroid glands secrete parathyroid hormones, resulting in the mobilisation of calcium in bone and increased phosphate excretion. These hormones act in unison to maintain calcium homeostasis.

Root resorption has been related to systemic disorders, including hyperparathyroidism,⁴⁹ hypothyroidism,⁵⁰ hypo- and hyperpituitarism,^{51,52} hypophosphatemia⁵³ and Paget disease.⁵⁴ In contrast, Linge and Linge suggest hormonal imbalances are not an aetiological factor *per se*, but rather, may serve to influence the resorptive process.⁵⁵ Similarly, Goldie and King did not support secondary hyperparathyroidism, created in response to parathyroid hormone (PTH) secretion in hypocalcaemic and lactating rats, as being primarily responsible for an increase in root resorption.⁵⁶ In fact, it has been demonstrated that increased bone resorption was associated with decreased root resorption. However, Engström observed an increase in amount of root resorption in hypocalcaemic rats both histologically and biochemically.⁵⁷

In contrast, hormones may also suppress root resorption. Sterol-treated rats demonstrated a reduction in orthodontic related root resorption compared with controls, thus suggesting steroid treatment reduces the activity of clastic cells.⁵⁸

2.1.6.1.5 Medical History

Asthmatics and allergy sufferers may be more susceptible to root resorption during orthodontic treatment.^{59,60} McNab et al⁵⁹ found an increased incidence of root blunting in asthmatics compared to a control group, using

orthopantomographic radiographs. The upper first molar teeth were found to be the most susceptible and it was suggested that inflammatory mediators produced in asthma might increase root resorption. Davidovitch et al⁶¹ correlated an increased risk of root resorption with asthma and allergies. Acute use of corticosteroid drugs in the treatment of such conditions has also been related to an increase in root resorption.⁶²

Medications such as bisphosphonates (inhibitors of bone resorption used in the treatment of osteoporosis) and calcitonin may also have a role in altered susceptibility to OIIRR.⁴⁶ Other medical issues such as alcoholism may also influence root resorption. Chronic alcoholics are possibly at an increased risk of developing the most severe grade of root resorption during orthodontics.⁶³ This is because ethanol inhibits the hydroxylation of vitamin D3, therefore preventing calcium homeostasis. This causes a rise in parathyroid hormone, which causes an increase in mineralised tissue resorption.

2.1.6.1.6 Nutritional Balance

A deprivation of dietary calcium and vitamin D in rats has been related to root resorption.⁵⁷ Engstrom et al⁵⁷ compared two groups of male Sprague Dawley rats – one fed a low calcium and deficient vitamin D diet and the other served as a control. Both groups were then treated with an expander

between their maxillary incisors after three weeks on their respective diets. Over a period of 14 and 21 days the rats were sacrificed. It was demonstrated that the group exposed to the diet deficient in calcium and vitamin D had hypocalcaemia, an increased alkaline phosphatase activity and higher systemic circulating parathyroid hormone, which is associated with an increased number of osteoclasts in the periodontal ligament.⁶⁴ Tooth movement was greater in this group, with rapid and more extensive bone resorption in the bony compression zone. It was concluded that the severity of root resorption increased after orthodontic treatment and related this to greater alveolar bone resorption.

However, other studies have suggested that nutrition plays only a minor role in orthodontic root resorption. Goldie and King found fewer root resorption craters in their study group of rats which were calcium deficient.⁵⁶

2.1.6.1.7 Age

Chronological aging has been associated with changes in dental hard and soft tissues. Changes such as a reduction in bone remodeling response, altered vascularity and increased cementum width may relate to an increase in root resorption observed in adults.^{14,65,66} However, other studies do not support this assertion.^{67,68}

Dental age may also influence a tooth's susceptibility to root resorption, in that open apices may better resist apical resorption.^{55,69} However, Hendrix et al found teeth with incompletely formed roots did not achieve what was considered a normal root length post-treatment.⁷⁰ Although this may be attributed to non-control of radiographic projection between pre- and post-treatment radiographs and such differences may be due to differences in study design.⁷¹

2.1.6.2 Tooth Related Factors

2.1.6.2.1 Dental History

The presence of root resorption prior to orthodontic treatment is highly correlated with the degree and quantity of root resorption during and after treatment.^{68,72}

Certain abnormal root forms have been related to an increase in orthodontic root resorption. This includes morphologically abnormal roots such as dilacerations, fine, and pipette-shaped roots^{16,18,73} and blunted or shortened roots,^{18,74} but excludes invaginations.⁷⁵ In contrast, other studies have demonstrated blunt root form is less susceptible to resorption.^{14,76,77} In a comparison between pointed, pipette, blunted, normal, dilacerated and incomplete root post-orthodontic treatment, it was shown that susceptibility

to resorption was most for dilacerated roots, followed by pipette and pointed roots.¹⁴

Traumatized teeth have been shown to have a greater loss of root length after orthodontic treatment.⁵⁵ However, traumatized teeth without a history of associated root resorption are not resorbed more than non-traumatized controls.^{33,78}

Root-canal treated teeth have been subject to conflicting observations. Wickwire et al showed an increased incidence of root resorption of endodontically treated teeth during orthodontic treatment.⁷⁹ Whereas, Mirabella and Artun⁸⁰ and Thilander et al⁸¹ oppose this view, and found less resorption. Remington et al., concludes that an increase in dentine density resists resorption.⁸² More recently, a review of 2,500 cases showed that there was no statistical difference in apical root resorption in endodontically treated teeth compared to vital teeth.⁸³ Therefore, teeth free of pulpal pathology and successfully treated non-vital teeth are at no greater risk of root resorption compared with vital teeth.

In addition to the tooth itself, the surrounding alveolar bone may also play a role in susceptibility to root resorption. Tooth movement through denser bone may increase root resorption.^{65,84} This may be attributed to fewer marrow spaces in dense alveolar bone, which means fewer resorptive cells

for bone remodelling.⁶⁵ Goldson and Henrikson found a two-fold increase in frequency and an eight-fold severity of resorption during Begg treatment due to the proximity of roots to compact cortical bone during Stage II treatment.⁸⁵ Conversely, Wainwright reported bone density has no relationship to the extent of resorption.⁸⁶ Vardimon et al⁸⁷ found that teeth located in dense buccal cortical plate in a subject group of monkeys demonstrated no more resorption than roots in less dense bone, thus concluding density was not a primary predisposing factor.

Malocclusion may be a risk factor predisposing root resorption. Increased overjet,⁸⁸ openbite⁷² and Class III malocclusions⁸⁹ have been associated with an increased risk. However, VonderAhe was unable to find a correlation between root resorption and different classifications of malocclusion.⁹⁰ Overbite has also been found to be unrelated.¹⁴

Non-physiological forces from habits such as finger-sucking,⁸⁸ nail-biting,²⁰ and tongue/lip dysfunction,¹⁸ may increase the risk of external apical root resorption.

2.1.6.2.2 Tooth type

Individual teeth have varied susceptibility to root resorption. Maxillary incisor teeth are most vulnerable to root resorption, but this may be due in

part to the distance they may need to be moved to establish a normalised position.^{11,66,90-92} The maxillary incisors are the most frequently affected teeth, laterals more than centrals, followed by the mandibular incisors, distal root of mandibular first molars and second premolars.⁹³ Other studies have also found the anterior segment more vulnerable compared to the posterior teeth, incisors experiencing more resorption than canines, and maxillary teeth being more affected than mandibular teeth.¹⁴

2.1.6.3 Mechanical and treatment Factors

2.1.6.3.1 Duration

Duration of treatment has been associated with increased risk and severity of apical root resorption.⁷¹ This has been demonstrated in human studies. Stenvik and Mjör, compared 35 experimental and control human premolar teeth from 10 to 13 year olds.¹⁵ The experimental teeth had forces of 35-250 g applied over 4 to 35 days. An increase in treatment time was associated with increased root resorption. Furthermore, it was concluded that duration of force application was more critical than force magnitude. Harry and Sims also examined human premolar teeth and determined root resorption by scanning electron microscopy, following the application of 50 g, 100 g and 200 g intrusive forces over 14, 35 and 70 days.¹⁷ They also found a

relationship between an increase in resorption and treatment time. Increased treatment time has also been shown to result in a greater width and depth of root resorption craters.⁹⁴

On the contrary, other investigations have not supported a correlation between increased root resorption and treatment time.^{90,95} Dermaut and DeMunck¹¹ intruded maxillary incisors with a modified Burstone Arch (0.018" Australian Wire) engaged in Begg brackets in a group of 20 patients whose ages ranged from 11 to 37 years. The intrusive force was in place for an average of 29 weeks. The extent of root resorption was determined using periapical radiographs and no correlation was found between extent of root resorption and duration of treatment.

2.1.6.3.2 Amount of tooth movement

The increase in incidence of root resorption of anterior maxillary teeth may be related to the distance these teeth are moved orthodontically.⁹⁶

2.1.6.3.3 Appliance Type

Removable appliances cause less root resorption compared with fixed appliances,⁵⁵ with Standard Edgewise being more detrimental than straight-wire techniques.⁹⁷ No differences have been demonstrated between sectional

and continuous mechanics⁹⁸ nor between Speed and Edgewise techniques.⁹⁹ There may be a difference between Begg and Edgewise, with Begg having less¹⁰⁰ or more⁸⁵ resorption, however Malmgren et al⁷⁸ found no difference. The amount of resorption is also similar for 0.018" and 0.022" slot brackets and steel compared to titanium archwires.¹⁴

The use of elastics may also have an effect on resorption. Intermaxillary elastics were shown to increase the amount of root resorption,⁵⁵ although Sameshima and Sinclair⁶⁶ found no difference. Class III elastics used for anchorage purposes have been demonstrated to cause resorption to the distal root of the mandibular first molar.⁶⁹

Rapid expansion has been related to root resorption. The use of rapid maxillary expansion appliances causes resorption of the anchor teeth.^{81,101} Conversely, Sameshima and Sinclair suggest there is no difference with expansion.¹⁴

2.1.6.3.4 Type of tooth movement

Intrusive movements appear to result in the most root resorption.¹⁰² Other tooth movements such as torque, tipping, maxillary expansion and translation can also cause root resorption,^{22,55,90,94} although there may be less root resorption with translation compared with movements involving tipping due to stress concentration.⁸¹

Force constancy is also another issue. There is no agreement as to whether continuous or discontinuous forces result in less root resorption. Intermittent force has been suggested to produce less resorption, with the cessation of force allowing time for recovery of the cementum.¹⁰³

Acar et al¹⁰³ used contralateral human premolar teeth with 100 g of continuous tipping force on one side and discontinuous force on the other over 9 weeks. It was concluded that discontinuous forces resulted in less root resorption. However, this study utilised force application via elastics, which therefore relied on patient compliance. In contrast, Owman-Moll et al¹⁰⁴ found no difference in the amount or severity of resorption. This study applied a buccally directed continuous and interrupted force of adolescent patients over a four and seven week period.

More recent volumetric studies of resorption areas have lent support to the relationship of increased resorption with an increase in buccal and intrusive force.^{105,106} Since OIIRR is part of the hyalinisation elimination process for a force directed, for example, in the buccal direction, it would be expected that the greatest changes in root mineral content would be at the cervical third of the buccal and apical third of the lingual surfaces.⁵ However, more recently it has been shown that significant tissue changes occur at both tension and compression areas.¹⁰⁷

2.1.6.3.5 Magnitude of orthodontic force

Optimal force has been defined as 26 g/cm^2 , beyond which ischemia of the periodontal ligament vasculature may trigger processes which inadvertently result in root resorption.¹⁰⁸ However, there is some disagreement regarding the relationship between the level of force and its effect on root resorption.

Owman-Moll and co-workers argue that there is large inter-individual variation.^{109,110} They found no differences in frequency or severity of resorption using 50 g compared to 100 g and 200 g of buccal force in adolescent human premolars. The experimental intervals were one month and seven weeks. Similarly, Reitan¹¹¹ found only a weak correlation between the extent of resorption and force using 25 g and 240 g of intrusion applied to human premolars. This experiment was also conducted in adolescents and was over a period of 10 to 47 days. However, these studies were conducted over a relatively short period.

In contrast to these histological and radiographic studies, which fail to support a relationship between force and root resorption, a number of animal studies have demonstrated an increase in root resorption with increased orthodontic force magnitude. King and Fischlschweiger¹¹² applied 50 g and 200 g of force in rats. Lighter forces were associated with less resorption. Primates have also been used in root resorption studies.

Dellinger¹¹³ used *Macaca Speciosa* monkeys and applied intrusive force to the upper first premolar teeth. The higher force groups of 100 g and 300 g showed much greater root resorption compared to the 10 g and 50 g groups. However, due to morphological and functional difference between animals and the human dentoalveolar structures, animal studies may not be directly applicable to humans. Importantly, animals have denser alveolar bone with reduced marrow spaces, and this may influence the resorptive process. Furthermore, rats demonstrate a consistent presence of root resorption even without exposure to orthodontic force.¹¹⁴

In support, experiments on human teeth have also shown a positive relationship between increased force and resorption. Electron Microscope technology has been used to demonstrate that higher force is associated with a greater volume of resorption craters. Harry and Sims¹⁷ used 50 g, 100 g and 200 g intrusive force and, following extraction and analysis with a scanning electron microscope, they concluded an increased rate of lacunae development. Casa⁹⁴ used 300 cN and 600 cN torquing force to maxillary first premolars, over a period of a month. High pressure zones are more susceptible to resorption.¹¹⁵ Areas undergoing high force (225 g) compression had significantly more resorption than areas under tension and other regions of the tooth root.¹¹⁶

2.1.7 Prevention, Management and Clinical implications of root resorption

There is currently no consensus on how or indeed whether, it is possible to prevent root resorption. Strategies have been suggested on how to possibly minimise root resorption. These include:

1. *Limit the treatment duration*^{15,16}
2. *Light and intermittent forces*¹⁷
3. *Assessment of medical history and familial tendency*^{18,19}
4. *Control habits*²⁰
5. *Halt treatment*^{21,22}

Where apical resorption is noted during treatment, cessation of force for two to three months reduced resorption compared to those who continued treatment.¹¹⁷ In general it has traditionally been recommended that radiographs be taken six months after treatment begins.¹¹⁸ For patients with blunt and pipette-shaped apices, a three month regimen of radiographic review is suggested.⁷³ More recent findings suggest a future for biological markers rather than radiographs to evaluate root resorption. Testing of gingival crevicular fluid for Dentine Sialoprotein and Dentine Phosphoryn

could be used as biological markers for monitoring root resorption during treatment.¹¹⁹

Where severe resorption has occurred treatment compromises will need to be accepted.¹²⁰ In extreme cases endodontic treatment may be required.¹²¹ Although a majority of patients experience some degree of root resorption, the risk of tooth loss is not increased.¹²² The equivalent loss of periodontal support at the crestal alveolar bone level compared to the root apex is disproportionate, with apical loss much less detrimental.¹²³ A tooth with 5 mm of apical root loss has 25% loss of periodontal attachment.¹²⁴

In the long-term, no loss of tooth has been reported.⁹⁰ The most extreme consequence of root resorption was increased mobility.⁸² It has been concluded that root resorption as a result of orthodontic treatment does not pose long-term harm to the patient's dental health.⁷¹ However, over a period of 5 to 15 years, where the remaining tooth structure is less than 9 mm, long-term mobility may continue.¹¹⁸

2.1.8 Cementum and resistance to root resorption

Cementum is similar to bone,¹²⁵ but behaves differently in response to orthodontic force application. Unlike bone, cementum is not fully resorbed. The exact mechanism of how it is able to resist resorption has not yet been elucidated. Explanations include:

1. Cellular barriers

Cells that form a covering over dental tissue may provide a barrier against odontoclasts. This has been demonstrated by the use of a replanted tooth as a root resorption model in monkeys.³³ The inner cellular layer of the periodontal ligament consists of cementoblasts, fibroblasts, osteoblasts, endothelial and perivascular cells. This is thought to provide a protective and repair mechanism.³³

2. Precementum

The precementum layer is an unmineralised matrix and has been thought to have a resistance to resorption.¹²⁶ Osteoid¹²⁷ and predentin¹⁵ are also uncalcified mineralised tissues and also demonstrate a reduced susceptibility to resorption.

3. *Mineral content*

The susceptibility of root resorption has been related to the degree of cementum mineralisation.¹² Henry and Weinmann found that cervically positioned acellular cementum is more mineralised and was more resistant compared to less mineralised cementum. Reitan and Rygh⁶⁵ reported cementum density may confer greater resistance to resorption. However, Jones and Boyde¹²⁸ do not believe mineral content of dental tissue influences susceptibility to root resorption.

2.1.9 Mineral content of teeth and its relationship to OIIRR

Literature directly examining the mineral composition of OIIRR craters in humans remains elusive. Element changes in cementum following orthodontic force have been studied,¹⁰⁷ but no direct examination of mineral composition of the resorptive lesions has been made. A study in the veterinary literature appears to be unique in its evaluation of the elemental composition of teeth with odontoclastic resorption lesions.²⁵ This study focused on cats. These lesions were described as idiopathic surface defects established by odontoclasts unrelated to caries. Since literature is sparse in this area of interest, from the description of this study, its findings may be

assumed to be somewhat equivalent to external inflammatory root resorption seen by the dental profession in human patients. Furthermore, the elemental composition of cat teeth is similar to humans.²⁵ This study used nuclear microprobe analysis and compared overall dental tissue of those suffering from resorptive lesions and normal cat teeth. They found teeth affected by this pathology had greater concentrations of sodium overall and less iron, whilst in cementum there was a significant reduction in magnesium and fluorine. No conclusions were made regarding clinical relevance. However, future studies focusing on diet, elemental composition of teeth and the development of such lesions to demonstrate a direct relationship was recommended. Although this study provides useful information, it is notable that there was no focus on minerals within the lesions themselves, and as per the usual limitations of standard microprobe machines, only provided "spot-scanning".¹²⁹

Root resorption remains an important consideration in orthodontics, as it is a common occurrence. Its aetiology, biological mechanisms, prevention and management are not yet fully elucidated. However, the accumulation of histologic, chemical and biological based research is contributing greatly to our understanding of this issue.

2.2 Cementum

2.2.1 Tooth root cementum

Teeth are supported within the jaw by four tissue layers – gingivae, periodontal ligament and alveolar bone and cementum.¹³⁰ Cementum is a mineralised layer overlying tooth dentine, covering the entire root surface.¹³⁰⁻¹³²

Cementum is adhered to dentine on its inner surface, whilst on the outer side it is continuous with the periodontal ligament. This serves its main function of providing attachment to the collagenous periodontal ligament fibres. Cementum is a dynamic tissue and its cells are responsive and adaptive.¹³³

Although cementum is similar to bone, chemically and physically, there are marked differences. Cementum does not have innervation and is avascular. It is also less readily resorbed compared with bone. This feature has been attributed to its unique physical and biological properties, pre-cementum, density of Sharpey's Fibres and location of epithelial cell rests.¹³¹ However, the composition of dental cementum has not been studied to the extent of other mineralised tissues.²³

2.2.2 Classification of cementum

Cementum has three classifications – (1) Time formation (Primary or Secondary), (2) Presence of cells (Cellular or Acellular) and (3) Cementoblastic or fibroblastic origin of collagenous fibres (Extrinsic, Mixed or Intrinsic Fibre Cementum).^{130,133}

Acellular cementum has no cells. It covers the cervical third of the root and its border with dentine is not clearly demarcated. Its rate of development is relatively slow and does not increase substantially with age. There is a virtual absence of pre-cementum. In contrast, cellular cementum has lacunae and canaliculi containing cementocytes along with their processes. It covers the apical two-thirds of the root and is clearly demarcated from dentine. Its rate of development is relatively fast and its incremental lines are further apart. Cellular cementum continues to form throughout life and is characterised by the presence of pre-cementum.

Extrinsic fibres are related to the periodontal ligament from where their cells are derived. Sharpey's Fibres continue into the cementum in the same direction as the principal fibres of the periodontal ligament, that is, perpendicular or oblique to the root surface. Intrinsic fibres are derived from cementoblasts. These run parallel to the root surface and approximately

perpendicular to the extrinsic fibres. Mixed fibres refers to when both intrinsic and extrinsic fibres are present.¹³⁴

The varieties of cementum have been categorised as follows:^{135,136}

1. Primary Acellular Intrinsic Fibre Cementum

This type of cementum assists in tooth attachment. Prior to periodontal ligament (PDL) formation, cementoblasts form a collagenous matrix. Following the formation of the first 15-20 μm , its fibres connect to the PDL.

2. Primary Acellular Extrinsic Fibre Cementum

This layer is the main source of attachment. All collagen is derived as Sharpey's Fibres from the periodontal ligament. These fibres are well mineralised at the point of insertion. Therefore, this layer exhibits a greater degree of mineralisation.²³ It covers two thirds or more of the tooth root.

3. *Secondary Cellular Intrinsic Fibre Cementum*

Absence of Sharpey's fibres means it has no role in tooth attachment. It may be found in patches in the apical region. This structure may be a temporary phase, with extrinsic fibres subsequently gaining reattachment, or it may represent a permanent region without attaching fibres. It generally corresponds to secondary cellular cementum and is found in the apical third of the root and in the interradicular areas. It is absent from anterior teeth. Although this type of cementum is generally cellular due to the rapid speed of formation, development is occasionally slower which results in cells not being incorporated. A cementoid layer is present. Both Acellular Extrinsic and Cellular Intrinsic Fibre Cementum may be present in alternating layers known as Cellular Mixed Stratified Cementum.

4. *Secondary Cellular Mixed Fibre Cementum*

Its function is adaptive and makes up the majority of secondary cementum present on a tooth. Where the formation rate is slow, cellular mixed-fibre cementum – which is generally less well mineralised – results. It is characterised by a laminated structure, cementocytes (located in lacunae with processes in canaliculi) and by the presence of a cementoid layer.

5. *Acellular Afibrillar Cementum*

This form of cementum may be regarded as a developmental anomaly and has no supportive or structural role. This is the only type of cementum which does not contain any collagen fibres. It is sparsely distributed, thin, acellular and consists of well-mineralised ground substance that may be of epithelial origin. It covers cervical enamel or intervenes between fibrillar cementum and dentine, which is thought to develop at this site following the loss of reduced enamel epithelium.

6. *Intermediate Cementum*

Located only at the apex. It features cellular debris and has no functional role.

7. *Mixed Stratified Cementum*

This type has a layered pattern of Acellular Extrinsic and Cellular Intrinsic cementum reflecting its role in the adaptive process. Cellular Intrinsic Fibre, Cellular Mixed Fibre and Cellular Mixed Stratified Cementum are located more apically and confirm microradiographic¹³⁷ and electron microprobe studies¹³⁸ which found that apically located cementum is less mineralised. This has been explained by the presence of non-mineralised structures, such as cementocyte lacunae, in the 'cellular' types of cementum.²³

2.2.3 Development

Cementum formation begins when root dentine formation commences, under the influence of Hertwig's Root Sheath. Cells from the dental follicle differentiate to become cementoblasts. These commence the synthesis of collagen and ground substance that form cementum. They also facilitate mineralisation similarly to dentine, and consequently hydroxyapatite crystals are deposited on the organic matrix. Cementum is formed slowly prior to eruption and is laid down in layers. This layering is seen as 'reversal lines' in adult teeth. Once the tooth erupts, cementum begins to form more rapidly, causing the entrapment of cementoblasts in the forming mineralised tissue. This in turn, results in the formation of cellular and acellular cementum. Cellular cementum is associated with a reduced fluoride content, as its rapid formation does not allow the time for its accumulation compared to that of acellular cementum.¹³⁹

2.2.4 Chemical properties

Cementum contains 22% water, 45% inorganic material and 33% organic material by volume. On a wet-weight basis it contains 12% water, 65% inorganic and 23% organic material.¹⁴⁰ However, cementum is not uniform.¹⁴¹ Different cementum types have varied degrees of

mineralisation.¹³⁵ The principal inorganic component is hydroxyapatite. The concentration of trace elements tends to be greater superficially. This includes the level of fluoride. Fluoride is in higher concentration in acellular compared with cellular cementum. The non-collagenous material is likened to that found in bone. The organic component is mainly collagen, most of which is Type 1. It has been noted that the percentage of dental root tissues' chemical components vary between samples, although the relative constituents are consistent within species.²³

2.2.5 Physical properties

Cementum thickness is greatest at the root apex, approximating 50-200 μm , and at the cervical region thins to 10-15 μm .¹³¹ The elasticity, density and hardness of cementum may impart important characteristics in its response to mechanical and biological stimuli.¹⁴² Microhardness has been tested using indentation and resin embedding techniques. Using the Micro Ultra-Indentation System (UMIS-2000; Campbell, Australia) Poolthong et al¹⁴³ determined that cementum had reduced hardness (0.8-0.9 GPa) and elasticity (11.5-12.1 GPa) apically. Cervically, the values of hardness (1.4-1.6 GPa) and elasticity (11.5-12.1 GPa) were higher. However, such requirements for tooth sample preparation may distort the accuracy of quantitative analysis. Malek et al¹⁴¹ overcame such limitations by using the UMIS-2000 programmed at 5 mN of contact force with a 20 μm diamond

indenter. The part of the tooth not embedded was oriented with a jig to allow identification in three planes of space. They found the cervical third was less hard than previously reported, 0.59 ± 0.05 GPa, and it had elasticity of 9.9 ± 1.5 GPa. The apical third had a value of 0.29 ± 0.12 GPa and elasticity of 3.99 ± 1.3 GPa.

The physical properties of cementum are dynamic in response to applied orthodontic forces, but reflect gradients seen in normal mineral composition. The trend of reduced hardness and elastic modulus from cervical to the apical end of the tooth is maintained after exposure to application of 25 g and 250 g buccally directed orthodontic force.¹⁴⁴ These observations are in agreement with the histological and physical properties of cellular and acellular cementum type distribution.

However, testing of hardness is only an indication of degree of mineralisation and does not provide information on individual percentages of elements.¹⁴⁵ Tooth mineral composition can be assessed using microprobes. Rex and co-workers used an electron microprobe technique to study the effect of force on tooth minerals.¹⁰⁷ When a tooth is exposed to light force (25 g) there is no apparent alteration in tooth mineral composition. However, a decreased mineral content of cementum has been demonstrated following increased orthodontic force.¹⁰⁷ Heavier forces (225 g) resulted in marked changes in mineral content. There was an increase in

calcium and phosphate in areas of compression, and a reduction in calcium in areas of tension. In contrast fluoride was inversely related to calcium and phosphate changes. With regards to fluoride, however, overall there was no significant difference between light, heavy or control teeth.

Various explanations may support the trend of altered of mineral content with orthodontic force:

1. *pH changes in microenvironment.* The inflammatory process involved in tooth movement results in the local drop in pH level, which could lead to dissolution of mineral content of the tooth root surface.^{146,147}
2. *Cell mediated response.* Lowering the pH of tissues results in increased activity of osteoclasts whilst inhibiting osteoblasts.³⁶ This mechanism may have a similar effect on odontoclasts and odontoblasts.¹⁰⁷
3. *Homeostasis.* Osteoblasts activate calcium channels, which lead to an increase in intracellular calcium, resulting in hypocalcaemia. Physiologic processes then act to restore balance.¹⁴⁸ In support, hypocalcaemic states in rats have been associated with an increased

severity of root resorption.⁵⁷ In contrast, Goldie and King⁵⁶ did not demonstrate the same findings.

Physical properties are a by-product of the mineral content. Quantitative assessment of calcium, phosphorus and fluoride concentrations demonstrate a reduction of mineral concentration towards the apex.¹⁴⁹ There is no difference between buccal and lingual surfaces, except for increased fluoride bucco-cervically. There is a significant difference between the upper half of the root compared to the apical part. Thus the mid-third of the root is assumed to reflect an average distribution of mineral content of the tooth root. However, the distribution of minerals within mature root tissue shows a great variability.²³

2.2.5.1 Presence of Calcium and Phosphate

Few studies have quantitatively detailed the distribution of minerals and elements of tooth roots and the majority have focused on crowns of teeth (Table 2.1). Calcium and phosphate have been shown to be distributed with no significant difference along the root surface.¹⁵⁰⁻¹⁵² However, there may be an increase of calcium and phosphate at the cervical cementum with age.¹⁵⁰ An explanation suggested was that this might be due to environmental exposure via the oral cavity. From the superficial layer of cementum towards the pulp, there may be an increasing concentration of

these minerals.¹⁵³ However, other studies have shown little difference.^{154,155}

Rex and co-workers, using an electron microprobe, demonstrated calcium and phosphate concentrations were the same buccally and lingually.¹⁰⁷

Whilst the concentration cervical to apical decreased, the converse was found for the outer to inner surface, which demonstrated an increasing gradient from the cervical to middle third. There was no difference at the apical third.

Percentage weight of calcium has been reported to range from 24.0% to 29.24% dry weight as a mean total.^{150,151,156} Percentage ash ranges from 35.6% to 42.4%.¹⁵² The mean percentage weight concentration has been shown to vary between root and region of root surface – buccal-cervical 30.05%, buccal-middle 28.63%, buccal-apical 27.16%, lingual-cervical 29.69%, lingual-middle 28.90% and lingual apical 26.96%.¹³⁸ Phosphate also varies in distribution through the tooth structure – buccal-cervical 13.70%, buccal-middle 13.16%, buccal-apical 12.35%, lingual-cervical 13.72%, lingual-middle 13.27% and lingual apical 12.28%.¹³⁸

Another study, which used electron microprobe analysis, reported very different results.¹⁵⁷ A calcium/phosphate ratio of 1.8-2.2% was recorded at the cemento-enamel junction, 1.65% at the coronal third, 1.3% at the furcation and 1.65-1.3% apically. Study design issues may limit the value of these figures. In particular, impacted third molars were used. The

preparation of these teeth involved root scaling to remove the periodontal ligament, which may have damaged the cementum. Furthermore these samples were not sectioned. Failure to provide a flat surface from which to project x-ray beams can result in significant background scatter¹⁵⁸ and thus may influence the results.

2.2.5.2 Presence of Fluoride

Fluoride has a varied distribution through and across the tooth surface. It also depends on age and environmental fluoride exposure. In general, there is an increase with age and ingestion of fluoridated water.^{152,159} The fluoride concentration was on average 45-65% ash weight.

Fluoride ion electrode has been used to study the concentration of fluoride in cementum. Nakagaki et al¹⁶⁰ examined the enamel and cementum in 20 premolars. The subjects were from areas with a community water supply which was fluoridated at 0.1 ppm or less. The superficial cementum contained a higher concentration of fluoride. There was an increase in cementum concentration of fluoride with age, which varied from 200-3000 ppm. Sugihara et al¹⁶¹ used the same methodology as Nakagaki et al¹⁶⁰ on 10 adult lower incisors. At the cervical region a fluoride concentration of 1509 ppm was recorded, and at the apex there was 1372 ppm. The fluoride concentrations increased with age. Also using the same methodology as the

previous two studies, Kato et al¹⁶² examined children between six to nine years old, who lived in an area with water fluoridation of less than 0.1 ppm. The average fluoride concentration ranged between 150-450 ppm.

The distribution of fluoride varies across teeth. Buccal-cervically it is present at 1.13%, buccal-mesially 0.91% and buccal-apically 0.62% wt, whilst on the lingual surface fluoride is distributed cervically at 0.96%, mesially 0.91% and apically 0.57% wt.¹³⁸

2.2.6 Dynamic Properties

Cementum is the tooth's dynamic interface to the periodontal environment. Mineralisation during development occurs on average at a rate of 3 μm per year, but depends on the cementum and tooth type being formed.¹⁶³ The mineral content post-development does not seem to change significantly with age.²³ This is not so for root dentine, whose tubules become obliterated with maturity.¹³¹

Similar to other hard tissues, hydroxyapatite in cementum is not pure and contains elements from its microenvironment.²³ Even though cementum is sometimes referred to as "bone-like" there are marked differences. Bone tissue actively participates in the physiological exchange of elements. In

contrast, cementum is mostly excluded from such metabolic processes.²³ This may be attributable to the specific non-collagenous proteins unique to cementum. In particular, the protein which mediates the attachment of connective tissue cells differs from bone sialoprotein and osteoprotegrin.¹⁶⁴ In addition is the cementum-derived growth factor.¹⁶⁵ Following root resorption, these proteins may be exposed and could possibly influence the initiation of the repair process.²³

The minerals in the circulating fluid can react with cementum. In particular, the fluoride ion reacts aggressively with hydroxyapatite.²³ In contrast, the opposing alveolar bone is constantly remodelled and thus does not accumulate such minerals to the same extent as cementum.

When the root surface is breached, repair matrices become attached to the resorbed surface.²⁴ Following the detachment of odontoclasts the cementogenic cells re-populate. Within their lacunae they initiate the attachment of the repair matrix to the thin decalcified layer of remaining collagen fibrils. The new matrix and original collagen fibrils then integrate. These repair cells and tissue matrices are homologous to the original root structure. This is followed by electron-dense globular accumulations indicating re-mineralisation. These events reflect those which occur during tooth root development.²³

Damage and subsequent repair to the mineral structure, in the form of dissolution of crystallite, also occurs. However, this process is usually countered by remineralisation. A dynamic exchange of minerals occurs superficially and this limits the extent of more minor resorptive defects. Subjacent unaffected tissue provides a reservoir for diffuse transition of elements.²³ A relative time-frame for re-mineralisation can be extrapolated from that measured for fluorine, which is incorporated into enamel within one hour from the microcirculation.¹⁶⁶

Therefore, the opposing hard tissues of cementum and bone are different chemically, physically and physiologically. Such differences may explain why cementum does not participate in general body metabolism and as a result remains unaffected by many pathologies which affect bone.²³ Cementum is dynamic and this is highlighted by its reparative properties.

| Study | Tooth type | Number of teeth analysed | Calcium (% wt) | Phosphate (% wt) | Fluoride | |
|--|----------------------------------|--------------------------|------------------------------------|------------------------------------|--|---|
| | | | | | F in H ₂ O | % wt |
| Neiders ¹⁵¹ | Premolars | 5 | Cervical: 25.62, Midroot: 26.04 | Cervical: 12.92, Midroot: 13.48 | Not specified | Not determined |
| Hals and Selvig ¹⁵⁴ | Variable | Not specified | Not specified | Not specified | Low-F area | Outer surface: 0.5-0.6, CDJ: 0.15. Overall 1.3-1.9 |
| Tödal and Hals ¹⁵³ | 2 Maxillary incisors, 1 premolar | 3 | 24.0 | 11.6 | Not specified | 0.37 (0.16-0.7) |
| Hennequin and Douillard ¹⁵⁶ | Mandibular third molars | 25 | Midroot: 29.24 ± 0.57 | Midroot: 13.49 ± 0.31 | Not specified | Not determined |
| Crawford, Sampson, de Bruin ¹⁶⁷ | Permanent Molars | 6 | Not determined | Not determined | Community water source for last 5 years, South Australia | 0.9-2.4 |

| | | | | | | |
|--------------------------|--------------------|----|--|--|--|--------------------------|
| Chaudhri ¹⁶⁸ | Type not specified | 15 | Not determined | 13.0% | Community water source, South Australia | Not determined |
| Rex et al ¹⁰⁷ | Premolars | 36 | Heavy force (HF): overall 27.69, cervical 28.87, middle 28.35, apical 26.95. Light force (LF): overall 28.91, cervical 30.75, middle 30.32, apical 28.59. | HF: overall 12.96. LF: overall 13.31. | Community water source since birth, NSW, Australia | HF: 0.859. LF: 0.830. |

Table 2.1 continued: Summary of microprobe studies on human cementum and findings of Calcium, Phosphate, Fluorine concentrations expressed in percentage dry weight (% wt).

2.2.5.3 Trace elements

Trace elements are present in cementum. However, it has been reported that their distribution and significance has not been studied in detail.²³ Manganese is present in 0.5-0.9% wt.^{151,152,154} However, higher values of 1.3-1.4% have been reported.¹⁵⁷ This ion is present in the hydroxyapatite crystal lattice. It has been suggested that magnesium could be important in contributing to cementum mineralisation and may play a role in controlling the growth of hydroxyapatite crystals.¹⁵⁷ Manganese increases from superficial cementum towards the cementodentinal junction.¹⁵⁴ Overall it is found at higher concentrations in the deeper root surface layers.²³ The concentration of manganese increases from the cervical region to apex and also increases with age.¹⁵² In contrast, an abrasive micro-sampling technique has demonstrated that the overall concentration remained unchanged over time.¹⁶⁹ The cementum fluoride concentration was found to be inversely proportional to magnesium,¹⁶⁹ whereas manganese is found in similar concentrations to calcium.²³

Citrate is also present in cementum and has been shown to be present at $0.86 \pm 0.06\%$ wt.¹⁵⁹ Carbonate is present in a concentration of 2.79% wt and for both these elements there is no inverse relationship with fluoride, unlike that observed in enamel.¹⁵⁹

The presence of zinc has been noted in cementum.^{170,171} Modulation of osteoclastic resorption of bone and dental tissue in the presence of zinc has been examined.¹⁷¹ It has been established that the lacunae developed on tooth cementum, in the presence of extracellular zinc, were fewer in number and had smaller surface areas.

Like zinc, strontium is another element which has been related to reducing bone resorption.¹⁷² The dental profession has used strontium in its desensitisation products, in order to occlude dentine tubules.¹⁷³ In addition, strontium found in water is incorporated into dental tissue.¹⁷⁴ There is conflicting evidence of the effect strontium has on cementum solubility. An increased presence of strontium has been shown to increase cementum and enamel solubility.^{175,176} However, it has also been shown to decrease solubility when administered in the presence of fluoride.¹⁷⁷ Furthermore, the effect of strontium in combination with fluoride appears to be therapeutically additive, whereby an increasing mineralisation and density of dentine effectively reduced tooth sensitivity.¹⁷⁵

Other elements have been found in cementum using an electron microprobe analysis. Sulfur is present in range from 0.1-0.3%, sodium is present at 0.3%.¹⁵⁴ Copper has also been found in cementum.¹⁷⁰

2.3 Fluoride

2.3.1 General

Fluorine is an element, of which fluoride is its ionic form. Fluorine has an atomic weight of 19 and is the most electronegative element on the periodic table. It is widely found in the environment, both in organic and inorganic compounds.

Fluoride is found in teeth and has played an important role in the dental profession since being highlighted by Browne in 1892 in relation to the development of quality enamel. In the 1930s, fluoride was introduced as a preventive regimen against caries. It was later that McKay made a correlation between higher levels of fluoride in community water supplies as an aetiological factor for “mottling”, or fluorosis.¹⁷⁸ In 1936 Dean established that levels below one-part per million would not cause fluorosis.¹⁷⁹ It is now wide-spread that industrialised countries fluoridate their water supplies to bring naturally deficient areas in line with the accepted 0.7-0.12 ppm range. The three major benefits for dental health commonly promoted are:

1. *Reduction in solubility of enamel by conversion of hydroxyapatite to fluorapatite.* The chemical formula being $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2 + 2\text{F}^- \rightarrow \text{Ca}_{10}(\text{PO}_4)_6\text{F}_2 + 2\text{OH}^-$ in the presence of low concentrations of fluoride. Higher concentrations of fluoride results in some of these ions being adsorbed onto the crystal surfaces but the rest combine with calcium ions from the lattice to form calcium fluoride, which liberate phosphate ions: $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2 + 20\text{F}^- \rightarrow 10\text{CaF}_2 + 6\text{PO}_4 + 2\text{OH}^-$.
2. *Direct inhibitory effect on oral micro-organisms.* This is achieved by interfering with their glycolytic pathway, reducing their acid output and carbohydrate metabolism, which results in a reduction of polysaccharides (i.e. plaque).
3. *Promotion of remineralization.* This occurs post-eruption to enamel.¹⁸⁰

Fluoride received through the water supply or diet is 93% absorbed. With most being excreted by the kidneys, the remainder is deposited into the mineralised tissues of the body – bones and teeth. Fluoride has a high affinity for calcium phosphate and therefore accumulates readily in the body. When fluorine binds, the apatite crystals of mineralised tissue increases, and thus results in increased resistance to solubility. In

mineralised tissues fluoride is not static, and is exchanged by diffusion into the surrounding tissue fluid, saliva or plaque.

Fluoride absorption in the body is via oral and gastrointestinal absorption and plasma fluoride. In plasma there are two forms – ionic and non-ionic forms. The ionic form is higher where there is increased fluoride intake. Plasma fluoride in rats is lower than humans. A fluoride water concentration of 100 ppm in rats is equivalent to 20 ppm in humans.¹⁸¹

Arguments against community fluoridation point out that with an excess of fluoride, side effects may occur which throw into question the safety of the product. Medical problems which may occur include skeletal fluorosis, which reduces joint mobility and causes discomfort in movement.¹⁸² It has also been linked to neurological changes and Alzheimer's Disease.¹⁸³ Safety concerns are related to the chemical structure of apatite which is $\text{Ca}_5(\text{PO}_4)_3\text{R}$, where the R-group can be fluoride, chloride or hydroxyl ion. Apatite is the main source of fluorides used in water fluoridation. To make the final product safe, silicon is added. Apatite is the raw material for the manufacture of phosphate fertilisers and is an aluminium by-product. However, safety policies in its manufacture are implemented and the sensible use of fluoride is supported world-wide by governing dental associations.¹⁷⁸

2.3.2 Fluoride and dentistry

Fluoride is an agent used by the dental profession primarily to prevent caries. Its effects are mostly utilised topically, rather than systemically.¹⁸⁴ However, even systemic sources, such as water fluoridation, are useful as a preeruptive source of fluoride as well as providing additional topical effects after eruption. All sources of fluoride that an individual is exposed to contributes to the “reservoir” of fluoride from which teeth can benefit.

In Australia there is naturally occurring fluoride in the water source ranging from 0.1-0.4 ppm, and in the large urban populous areas has been increased to meet 1.0 ppm. The New South Wales Sydney Water Department Annual Report 2006 specifies that 95% of samples taken over a year should have 0.9 to 1.5 mg/L of fluoride in the community water system of this State. Concerns regarding dental fluorosis have focused on the additive effects of fluoride gained through substances other than the community water supply. Dental fluorosis is a “qualitative defect in enamel”, which is the result of increased ameloblasts during enamel formation.¹⁸⁴ Clinically this is seen as white flecks in its mildest form, to severe mottling and porosity of the defective outer tooth surface. On an extreme level, fluoride can also be toxic. A dose of 2 mg daily, during the time of tooth formation, will produce fluorosis, and 5 mg/kg is a probable toxic dose (Commonwealth Department of Health, Australia 1985). Thus, if fluoride supplements were to be

recommended for therapeutic purposes, all sources of fluoride that the individual may be exposed to need consideration. In an orthodontic demographic (adolescents and adults) exposure is likely to be in the form of toothpastes (1 mg F/g paste), mouth rinses (approximately 0.05% NaF), food (0.81-1.46 mg) and beverages (including water, 1.10-1.89 mg). On average it is estimated an adult will consume 2.13-3.95 mg of fluoride in a day (Commonwealth Department of Health, Australia 1985).

Systemic fluorides are available in drops and tablets. This regimen is usually limited to those of high caries risk. Tablet forms are recommended to be chewed, rather than swallowed, to maximise topical effects. However, there is an interest in systemic fluorides for use other than for caries, such as its potential role in prevention of endodontic related and orthodontic root resorption.²⁶

2.3.3 Fluoride and its relationship to cementum

Fluoride concentration in teeth is higher than in bone, and is highest in the cementum.¹⁵² Fluoride distribution varies across the surface and depth of teeth.¹³⁹

Fluoride gradient in rats has been demonstrated. Kato et al¹⁸⁵ used experimental groups given 25, 50 and 100 ppm fluoridated water over 10 weeks. This was compared to a control group that was given distilled water. Fluoride was found to be highest pulpally and reduced to the cemento-enamel junction. At this point it then increases to the root surface. The fluoride concentration increases with increased concentration of systemic fluoride.¹⁸⁶ Other rat studies have shown similar results. Ito et al¹⁸⁷ looked at the effect of the cessation of fluoride intake and found that there was a reduction in concentration in the superficial surfaces.

Fluoride distribution in rat teeth has been shown to be similar to human teeth. In human teeth there is an increasing gradient from inner to the outer surface of tooth roots.¹⁴⁹ Mineral composition on the buccal root surface demonstrated a fluoride distribution, which was greater cervically, and had a reduced concentration towards the apex. Otherwise, there is no difference in gradient of calcium, phosphate or fluoride concentrations between or across tooth surfaces.¹⁴⁹ That is, from outer to inner surface of the tooth and from cervical to apical thirds of the tooth there is decreasing concentrations of these elements. Furthermore, such distribution remains consistent, even when the tooth has been exposed to forces up to 225 g.¹⁰⁷ A suggested reason as to why studies have demonstrated an increased concentration of fluoride cervically is due to greater exposure via topical distribution through tooth exposure in the oral cavity.¹⁵²

2.3.4 Use of fluoride to protect teeth against root resorption

Studies examining the role of fluoride and its influence on root resorption have been in the area of endodontics and dental trauma. Research has mainly focused on the protocol following tooth avulsion. It may be beneficial to treat teeth with fluoride to minimise future potential resorption, as investigated by Coccia.¹⁸⁸ This study used 129 teeth, which had been avulsed in children. These teeth had closed apices and were reimplanted more than 12 hours after the incident. Two groups were studied, those teeth stored in saline were compared to those treated with 2% neutral sodium fluoride. Endodontic treatment was provided. It was found the teeth treated with fluoride were less susceptible to root resorption, but this was a function of extraoral storage time. These results have been supported by other studies on human teeth.¹⁸⁹

Animal studies have shown similar results. In monkeys, storage of avulsed teeth in 1M of sodium fluoride for 18 to 54 hours was effective in reducing root resorption.¹⁹⁰ In rats, Bjorvatn and Massler¹⁹¹ found that even a 2% sodium fluoride or 1% stannous fluoride solution of 5 minutes was effective in reducing resorption after three years. However, Barbakow et al¹⁹² cautioned against immersion in 2% acidulated sodium fluoride for 30 minutes, as after three weeks resorption was seen similar to the control

group and after the fourth week ankylosis occurred. The concentration of fluoride may also have a negative effect, with a 10% stannous fluoride solution found to inhibit normal healing processes.¹⁹³

The effect of fluoride on mechanical injury to the periodontium has been investigated.¹⁹⁴ Injury to rat tooth roots was achieved using a needle to puncture the cementum at the level of the gingival margin every three hours, for three times, over one day. The group receiving systemic sodium fluoride (25 mg/kg) via a gastric tube showed a reduced extent of trauma and root resorption. A conclusion was made that fluoride suppressed the root resorption induced by the injuries to the periodontal tissues.

Literature has been sparse examining the direct relationship of fluoride's potential protective influence and the effect mineral content of cementum may have against orthodontic associated root resorption. Foo et al²⁶ used rats to induce orthodontic root resorption and exposed part of the sample to systemic fluoride, with an estimated intake of 1 mg per day. It was demonstrated that the average crater volumes of teeth exposed to fluoride were about half the size. This was also evident in the group exposed to no orthodontic force but were given fluoridated drinking water. However, due to a large variation in results these differences were not significant at a level of $p > 0.05$ (Figure 2.3). This study was limited as it only examined pooled volumetric data for craters on each tooth. Further examination, with respect

to both individual craters, and discriminating between length and depth parameters may yield more information.

Figure 2.1: Box plot graph of resorption craters (volume) in experimental groups. (Source: Foo et al., 2007, with permission)

2.3.5 Mechanism of fluoride and its relationship to OIIRR

Although, fluoride does not increase the physical hardness of cementum *per se*,²⁷ there are a number of possible mechanisms that fluoride may impart a protective effect against orthodontically induced root resorption (as opposed to its well described effects on bone resorption):

1. *Direct effect on osteoclasts:*

- a. Osteoclastic activity has been shown, in culture, to alter in the presence of fluoride¹⁹⁵
- b. Osteoclastic secretory function is suppressed¹⁹⁶
- c. Furthermore, this affects the release of calcium and magnesium, thus the subsequent pattern of osteoclast adherence and motility is altered.¹⁹⁵ Fluoride has been observed to inhibit the activity of adjacent resorbing cells.¹⁹⁷
- d. Fluoride may also promote osteoblastic activity¹⁹⁸

2. *Alteration of shapes of resorption pits:*

- a. Resorption pits made by osteoclasts are shallower but wider.¹⁹⁵

3. *Mineralisation of cementum:*

- a. Fluoride is taken up by the root surface of teeth¹⁹⁸
- b. Cementum incorporates fluoride into its mineral lattice converting hydroxyapatite to fluorapatite¹³¹
- c. The increased crystallite size is more resistant to dissolution.^{199,200}

Fluoride's effect on osteoclasts depends on the dosage level. Sodium fluoride at 0.5-1.0 mM on a local level reduces the number of resorption lacunae made by individual osteoclasts and reduces the resorbed area. This is achieved from an intake of approximately 1 mg NaF/kg body weight per day in rabbits.²⁰¹ The inhibition of osteoclastic movement and a reduction in depth of resorption pits resulted from 15 mg/l NaF in rats.¹⁹⁵ A similar effect was achieved using 15 mg/kg for 21 days in another study.²⁰² A single high dose of fluoride was found to decrease osteoclast density and reduce the number of active osteoclasts whilst increasing inactive ones not attached to the bone surface.²⁰³

An understanding of the chemical and biological structure of cementum is vital, as it is the interface at which OIIRR occurs. The elemental composition of cementum may play a role in the extent and severity of the resulting lesion. An understanding of the effect root resorption has on minerals may also lead to potential preventive measures being elucidated.

2.4 Methodological considerations

2.4.1 Methods used in Orthodontically Induced Inflammatory Root Resorption studies

Animals have been used in the investigation of root resorption. Differences in the animal model pertinent to root resorption is that alveolar bone is denser and root resorption is prevalent in teeth which have not had force applied.²⁰⁴

Ideally, samples from human teeth would better represent a clinical situation. However, due to ethical considerations and suitability of patients for such trials there is limited access to such teeth. Furthermore, human fluoride consumption cannot be strictly controlled as fluoride is an abundant element in the environment.²⁰⁵

2.4.2 Sample Preparation and storage

Minimal preparation in studies which analyse tooth mineralisation is recommended, especially for cementum, which is a complex heterogenous connective tissue.²⁰⁶ Testing the physical properties of teeth and limitations

of machines employed mean that specimens often require embedding in resin. This procedure itself may alter the physical properties of cementum by dehydration from the exothermic setting reaction and inflow of resin into the specimen.²⁰⁷ Certain inexplicable findings in electron microprobe analysis of mineral content of cementum have been attributed to specimen preparation.¹⁰⁷ Consequently, studies have attempted to use techniques which minimally prepare tooth specimens.²⁰⁸

Methods which bypass the embedding process, yet allow sections of calcified tissues to be obtained are more ideal for studies examining mineral distribution and content. Freezing samples prior to sectioning is a method that has been previously used. It was shown that calcified tissues were satisfactorily preserved, whilst allowing for thin sections of sample to be taken.²⁰⁹

Another consideration, in addition to preparation of sample teeth, is how the samples are stored. Various storage media have been used for teeth. Purified and filtered water has been found to be appropriate for enamel and dentine. In this media it was found to cause the least changes to surface chemistry and optical properties, compared to distilled water plus thymol, phosphate-buffered saline with thymol, 70% ethanol, and 10% buffered formalin.²¹⁰ With regards to minimal mineral effects to cementum Milli-Q[®] (deionised water, Millipore, Bedford, Mass, pH = 7.2) is an appropriate media for

cleaning and storage up to nine months.²⁰⁸ The reason why different storage media have varied effects upon surface hardness and mineralisation is that for hydroxyapatite, adsorption, diffusion and dissolution are determined by the surface charge and electrochemical nature of the ionic solid. The charge develops as a consequence of reactions when the tooth is suspended in aqueous solution, which in turn depends on the pH of the media. Milli-Q[®] and alcohol are close to physiologic pH, whereas other media such as Miltons[®] solution has a pH of 9.5. Absence of storage media, leading to desiccation, can alter the physical properties of dentine. However, such changes are reversible upon rehydration.²¹¹

2.4.3 Microprobe

The advantage of using a microprobe is that it is possible to relate the distribution of elements to the physical structure of the tissue specimen.¹⁵³ Previous studies in the dental field have employed this mechanism to study elements in tooth roots, and it is suited to quantify the mineral content of teeth.²¹² However, the electron microprobe machines used in the past were limited. The machine and computer programme to be used in this present study is unique in its ability and accuracy for detecting trace elements.²¹³ Such results, from the nuclear microprobe (NMP) developed at the Commonwealth Scientific and Industrial Research Organisation (CSIRO), and the Australian Research Council's National Key Centre for

Geochemical Evolution and Metallogeny of Continents (GEMOC), to examine root resorption craters have not been previously presented, as verified by the machine's operators.

2.4.3.1 General introduction to nuclear microprobes

In the late 1970s, Harwell was frustrated by low current density attainable by unfocused MeV ion beams used for analysis of small regions. Such analysis required extremely long measurement periods. Harwell went on to develop a method to focus high-energy ion beams with quadrupole lenses. This then provided a useful large beam current density from which analytical methods could be produced. By mid-1990s 40 different types of nuclear microprobes were available worldwide.

The nuclear microprobe has developed as a result of techniques commonly used in material sciences and geology. These techniques employed proton induced X-ray emission (PIXE) and proton induced γ -ray emission (PIGE) which are surface analytical techniques for mapping multiple trace elements at micron resolutions.

2.4.3.2. Principles and Components of a NMP

A nuclear microprobe analysis requires the generation of high-energy proton beams in a tandem accelerator. This is used to systematically scan the surface of the sample. When the protons collide with surface sample atoms the result is a number of reactive products. These products are characteristic x-rays, secondary electrons, gamma rays and transmitted and backscattered protons.¹³²

During analysis the core electrons are ejected from a sample atom, causing destabilisation. In order to restore the stability of this atom, an outer shell electron drops into to the lower shell to occupy the vacancy. In doing so, there is a release of x-rays, which are characteristic for each element present in the sample. The x-ray wavelength is an identifier of the elements present in the sample, whilst their intensity describes the concentration.²¹⁴

Each nuclear microprobe worldwide has different components and configurations, thus this discussion is now limited to the machine used in the present study, namely the NMP developed at the Commonwealth Scientific and Industrial Research Organisation (CSIRO), and the Australian Research Council's National Key Centre for Geochemical Evolution and Metallogeny of Continents (GEMOC) (Figure 2.1).

Figure 2.2: CSIRO-GEMOC NMP (NMP) Machine Commonwealth Scientific and Industrial Research Organisation (CSIRO), Melbourne, Australia.

This instrument delivers a proton beam via a 3 MeV tandem accelerator. Which is collimated by divergence and object slits. Object slits are formed by 5 mm tungsten rods, which are configured in a “v-shape”. The slit can vary from 0-1200 μm . The object slits are located 2.6 meters from the divergence slits. The divergent slits are made of 1 mm thick tantalum plates which are motorized to allow linear movement. The degree of aberration in the focused beam-spot at a specific beam current can be adjusted, by using the slit gaps and altering the distance between the object and divergence slits.¹²⁹

The lens system is used to focus the protons into micron dimensions ready for scanning across the sample. The CSIRO-GEMOC NMP uses a unique quintuplet magnetic quadrupole lens system. This offers the advantage of achieving high demagnification with a short overall system length of 4.7 meters.¹²⁹ It is desirable to focus the MeV ions into 1 μm diameter probe, or smaller. This is difficult to achieve. A single magnetic quadrupole lens acts on the beam by contracting it, then expanding it. As it travels through the system, however, it accumulates aberrations. It is most desirable to have a lens with the largest demagnification with a short image distance.¹⁵⁸ The machine to be used in this study is able to achieve this.¹²⁹

The resultant x-rays from the scanning of the sample are detected by a germanium solid-state detector (Ultra LE Ge, Canberra, USA). This is

located 16 mm from the target. It has a 100 mm² aluminium filter that is 10 µm thick with a 32 µm beryllium window. A second x-ray detector identifies the major elements. Each individual emission co-ordinates are marked in two dimensions, enabling elemental distribution images to be recovered.

The magnitude of the background radiation produced determines the detection limits of the NMP. In particular, this technique generates Bremsstrahlung or braking radiation through target nuclei scattering. However, this magnitude is lower compared to background radiation produced by electrons. Therefore, the NMP has a much better detection limit than an electron probe.¹⁵⁸ Method Detection Limits (MDL) are calculated using Poisson statistics with the equation: $MDL = 3.26 \sqrt{2B}$, where B is the background.²¹³

2.4.3.3 Advantages and Limitations of NMP Analysis

Compared to other available techniques, the CSIRO-GEMOC NMP provides superior trace element spatial (resolution of 1-2 µm) and quantitative analysis. The NMP has low detection limits for the elements found in teeth and is better than other non-destructive techniques, which include the electron probe and energy dispersive X-ray analysis. Traditional

electron probe techniques only provide point-analyses. Furthermore, the NMP being used analyses a number of elements at any one time. The result is therefore quantitative multi-element data. However, the most valuable aspect of using this machine is by far the minute detail which is generated. The machine takes up to 12 hours to scan the surface of a single sample, depending on the detail required. Therefore, this technology does not lend itself well to bulk sample analysis. Rather, the data gathered is respected for its high quality.

The NMP is a non-destructive analysis with regards to both the beam itself and the method by which samples need to be prepared. The beam has very little energy over the first 30 μm . The sample requires minimal preparation compared to other techniques.²⁰⁶

The limitations of the NMP arise primarily from the extremely high expense to run samples through the machine and its limited accessibility. In addition, a high level of operator expertise is required to operate a NMP. The only machine available which is more sensitive to elements than the NMP is laser ablation (LA-ICP-MS).²¹⁵ However, laser ablation destroys samples and only provides the results of total concentration. It also cannot be used for isotopic analysis. This is a major limitation for elements in human teeth found to be below 1 ppm (such as lead). Furthermore, interferences from neighbouring elements may contaminate the signal of the element of

interest. Another current disadvantage is the inability for this machine to detect phosphorus with accuracy. The system is not calibrated for this element, but this issue is in the process of being addressed for the near future. Electron microprobe machines are more valuable in establishing concentrations for this particular element.

Currently, there is no available technique that can scan and detect elements on a non-flat surface. Three-dimensional elemental technology would be ideal, as all root resorption craters on a tooth could be assessed with minimal interference by tooth preparation. The NMP is no exception to this limitation. This means that teeth must be sectioned and polished to a flattened surface, allowing reflection of gamma and x-rays. Thus realistically only one crater per tooth can be scanned. Furthermore, analysing a non-uniform structure means that as the sample thins down (for example at a tooth's apex) the proton beam, which penetrates 60 μm into the sample, may reach the opposing surface. In teeth, this means that the results could be skewed towards higher values where dentine readings may include minerals present in underlying cementum.

It is essential that research analysing mineral content of biological structures employ techniques that allow the samples to remain chemically and physically unaltered. The CSIRO-GEMOC NMP is able to analyse calcified samples and meet such specifications better than other current techniques.

4.1 Abstract

Introduction: Root resorption resulting from orthodontic treatment is an unpredictable adverse effect. There is currently no consensus on how to minimise or prevent the development of this problem. Literature examining the potential protective influence of tooth cementum minerals against orthodontically induced inflammatory root resorption (OIIRR) has been sparse. Fluorine may be extrapolated as an important element, and could have a role in minimising the extent and severity of resorptive lesions. The present study appears unique in its aim of examining the elemental content of tooth cementum within OIIRR lesions and the effect of systemic fluoride.

Method: Two groups of seven week old Wistar rats were divided and exposed to systemic fluoride (100 ppm) or non-fluoridated drinking water ($n = 20$). The experimental period lasted two weeks. Orthodontic tooth movement was implemented by a Nickel Titanium closing coil with a force of 100 g. The molar teeth were then dissected and prepared for cross sectioning through the largest mesial mid-root crater. The samples were then mounted and scanned using the Commonwealth Scientific and Industrial Research Organisation and the Australian Research Council's National Key for Geochemical Evolution and Metallogeny of Continents Nuclear Microprobe (CSIRO-GEMOC NMP) and deconstructed using its associated software. An analysis of variance was

used for statistical comparison of elements and to determine the effect of fluoride, and unaffected tooth structure compared to root resorption craters. A student t-test was used to compare root crater lengths and depths of the Fluoride versus No-Fluoride groups.

In order to examine elemental content of teeth minimal sample preparation and a non-destructive analysis technique is ideal. The NMP used satisfied these criteria and provided spatial (resolution of 1-2 μm) and quantitative elemental measurements.

Results: Root resorption lesions of the group exposed to fluoride were significantly reduced in length and depth ($p < 0.01$). The mineral content of root resorption craters of the Fluoride group had higher concentrations of fluorine and zinc ($p < 0.01$). There was less calcium in craters of the No-fluoride compared with the Fluoride group ($p < 0.05$).

Conclusion: Cementum quality (influenced by systemic fluoride exposure) may impact the extent of orthodontically induced resorptive defects.

4.2 Introduction

Root resorption resulting from orthodontic treatment is an unpredictable adverse effect involving transient inflammatory surface resorption. This process has been termed Orthodontically Induced Inflammatory Root Resorption (OIIRR).¹ The mechanism of OIIRR has not been fully elucidated. Following orthodontic force application, tooth movement is associated with a local compression of the periodontal ligament and the development of sterile necrosis.² This morphometric phase is followed by biochemical changes. The sequence of events involves fibre coalescence, hyalinisation, degradation of connective tissue matrices (extracellular and intracellular pathways)³ followed by dissolution of Sharpey's fibres⁴ and finally odontoclastic activity. The resorptive process initially occurs at the circumference of the necrotic hyalinized area. This is followed by resorption of the root surface in the central part of the necrotic zone.⁵ The later stages also demonstrate areas of peripheral repair.^{6,7}

Associated risk factors for increased incidence of root resorption have been suggested to include: individual susceptibility, genetics, hormonal imbalance, medical history, nutritional balance, age, dental history, tooth type, duration of

treatment, amount of tooth movement, appliance type, type of tooth movement and magnitude of orthodontic force.⁸

There is currently no consensus on how to, or indeed whether it is possible to, prevent root resorption. However, strategies have been suggested on ways to possibly minimise root resorption. These include: limiting treatment duration,^{9,10} using light intermittent forces,¹¹ assessment of medical history & familial tendency,^{12,13} control of habits¹⁴ and, if required, cessation of treatment.^{15,16}

Literature has been sparse examining the direct relationship of fluoride's potential protective influence and the effect mineral content of cementum may have against orthodontic associated root resorption. Foo et al¹⁷ used rats to induce orthodontic root resorption, and exposed part of the sample to systemic fluoride, with an estimated intake of 1 mg per day. It was demonstrated that the average crater volumes of teeth exposed to fluoride were about half the size. However, due to a large variation in results these differences were not significant at a level of $p < 0.05$.

The present study appears to be unique in examining the elemental content of OIIRR craters. Such information may increase our understanding of this process and the possible protective effects that elements, such as fluorine, may impart to cementum.

Although fluoride does not increase the physical hardness of cementum *per se*,¹⁸ there are a number of possible mechanisms whereby fluoride may impart a protective effect against orthodontically induced root resorption (as opposed to its well described effects on bone resorption). These include: direct effect on osteoclasts, alteration of shapes of resorption pits and the mineralisation of cementum.¹⁹ Thus fluoride may be extrapolated as a potential preventive agent against the severity of OIIRR.

There are various methods to study elemental composition of teeth. The nuclear microprobe employs proton induced X-ray emission (PIXE) and proton induced γ -ray emission (PIGE), which allows mapping of multiple trace elements at micron resolutions. Compared to other available techniques, the Commonwealth Scientific and Industrial Research Organisation and the

Australian Research Council's National Key for Geochemical Evolution and Metallogeny of Continents Nuclear Microprobe (CSIRO-GEMOC NMP) provides superior spatial resolution (1-2 μm) and quantitative data on elemental concentrations. As yet this machine has not been used in the study of cementum root resorption lesions.

The aim of this thesis was to develop a methodology to use the CSIRO-GEMOC NMP in order to analyse the elemental composition of root resorption craters following the intake of systemic fluoride. Furthermore, potential preventive mechanisms and/or risk factors for orthodontic root resorption were examined in relation to the findings.

4.3 Materials and Methods

4.3.1 Sample

This study used twenty seven-week old female Wistar rats (Westmead Hospital Animal Ethics Committee, Project: 134.12-03). The rats were allowed one week to acclimatise to their new laboratory environment. They were then randomly divided into two groups of 10 animals. Group One had orthodontic tooth movement and received deionised water, which was not fluoridated. Group Two had orthodontic tooth movement and received fluoridated deionised water (100 ppm). Sodium fluoride was dissolved into Milli-Q[®] (deionised water, Millipore, Bedford, MA, USA) to meet this concentration level. Water was given *ad libitum*. Every two to three days, the water was monitored and replenished as necessary.¹⁷

4.3.2 Laboratory Procedure

4.3.2.1 Orthodontic tooth movement

Orthodontic tooth movement was implemented by use of a Nickel Titanium (NiTi) 100 g closing coils (NiTi 10-000-06, GAC International Inc, USA). The

NiTi coil was ligated to the rat's left first mandibular molar by means of a silk suture. The coil was activated via ligation to the mandibular incisors with steel ligatures (Figure 1).¹⁷ Attachment of the nickel titanium coils was performed under anaesthetic. The rats were administered a gaseous anaesthetic agent (Halothane), followed by the anaesthetic agents Xylazine (10 mg/kg) and Ketamine (90 mg/kg).

The experimental period lasted two weeks. After which the rats were sacrificed, using carbon dioxide. Their mandibles were dissected and sectioned mesial and distal to the left first mandibular molar. The samples were stored in Milli-Q®. This has been shown to have an insignificant effect on leaching of trace elements from cementum samples.^{20,21}

4.3.3 Sample Preparation

4.3.3.1 Dissection and preparation of rat first molar teeth

The teeth were progressively dissected, with the aim of minimising fracture of the fine rat molar roots and avoiding contact below the cemento-enamel junction, from the segment of mandible. This was achieved by severing any

remaining marginal gingivae, and then removing approximately one-third of the alveolar bone surrounding the tooth followed by luxation using a blunt-ended periosteal elevator. The dissection was carried out under a light-microscope (WILD M3B[®], Heerbrugg Switzerland). Following dissection the teeth were cleaned with sterile gauze soaked in Milli-Q[®] and gross periodontal ligament fibres manually removed with tweezers.²² The teeth were then stored in Milli-Q[®] at ambient room temperature ($23^{\circ} \pm 1^{\circ}$).²⁰

4.3.3.2 Locating root resorption craters

All root resorption craters were located on each tooth using an Olympus SZCTV microscope[®] (Tokyo, Japan). The largest mid-root crater on the mesial root of each tooth was identified. Reference points and co-ordinates were established and measurements (of the length and midpoint for each crater) were made using the AnalySIS[®] software program and a micrometer (μm) ruler. Measurements were made to the nearest 1 μm . Using an Olympus ColorView 2[®] camera, a true image of this crater was recorded.

4.3.3.3 Specimen sectioning

A “Wax Marker System” was developed by the author to indicate the point at which the tooth required sectioning. This achieved the goals of marking a microscopic point, which could be seen macroscopically for hand sectioning and allowing minimal interference with tooth minerals. The initial microscope photographs allowed re-location of the midpoint of the root resorption crater of interest (Figure 2).

This technique involved softening the centre point of approximately 1 x 1 cm² sheet of wax (Moyco Union Broach™ Dental wax) with hot water delivered via a pipette. Under microscopic view the wax was pushed over the tooth root to the point of sectioning (Figure 3).

The tooth was then floated in Milli-Q® crown-down in ice-cube trays (Figure 4). These were then frozen for 24 hours. The wax was removed, leaving the exposed root portion to be cut and the exact point/region of interest embedded in the Milli-Q® ice-block. Specimens were then sectioned transversely (Figure 5), in layers from the apex, through to the identified mid-point of the root resorption crater. This was achieved using Fine and Superfine Sof-Lex Discs™ (3M) under Milli-Q® irrigation, to a surface polish of <0.2 µm.

4.3.3.4 Root resorption crater dimensions

Using the Olympus SZCTV microscope[®], AnalySIS[®] software program and a μm -ruler, measurements were taken to determine the depth of the sectioned craters to complement the measurements of maximum length taken previously. A line was constructed from the two points marking the outer edge of the root resorption crater. Lines were then drawn perpendicular to the constructed line to establish the deepest point of the crater.

4.3.3.5 Specimen preparation for NMP

The specimens were then mounted on glass slides with a double-sided carbon adhesive tape. The slide and specimens were carbon coated (evaporated) in a vacuum at 10^{-4} Torr with an approximately 20 nm layer. The glass slide was then encased in a metal stub designed specifically for the NMP (Figure 6).

4.3.4 Sample Analysis

4.3.4.1 NMP

The spatial distribution of multiple elements based on x-ray and gamma ray emissions was measured in the resorption craters and surrounding non-resorbed cementum of the sample tooth-roots. This study used the NMP developed by the Commonwealth Scientific and Industrial Research Organisation and the Australian Research Council's National Key for Geochemical Evolution and Metallogeny of Continents (Melbourne, Victoria, Australia).

The analysis was performed with 3.0 MeV protons and the beam focused at $1 \times 1.8 \mu\text{m}^2$. Scanning was electrostatically driven in the Y-axis between 800-1500 μm with the stage stepped in the x-axis (step-size of 2.5 μm) to generate a rectangular image. The beam current was maintained at 4 nA. The total accumulated charge for average size area was approximately 20-25 μC . An aluminium absorber of 100 μm was used between the target and Germanium (Ge) detector (Canberra Ultra-Ge Detector[®]). Software to evaluate spectra was Geo-PIXE II[™] Version 3.8. The elements detectable under gamma rays were Sodium (Na), Fluorine (F), Manganese (Mn), Aluminium (Al) and Silicon (Si). Whilst under x-rays Calcium (Ca), Iron (Fe), Nickel (Ni), Copper (Cu), Zinc

(Zn), Bromine (Br), Rubidium (Rb), Strontium (Sr), Tin (Sn), Barium (Ba) and Lead (Pb) were measurable.

4.3.4.2 Analysis of data using Geo-PIXE II™

Geo-PIXE II™ Version 3.8 Computer Program was used to extract the raw data generated by the scanning process (Figure 7).²³ A manual analysis of regions, to provide quantitative data, was conducted by a function that allowed shapes to be drawn over the downloaded image. The regions analysed were a “traverse” through the middle of the deepest point of the root resorption crater and adjacent cementum. Readings from dentine below the crater, at the crater marginal cementum, as well as corresponding areas of distant physically unaffected root structure, of the same tooth surface, were recorded (Figure 8). This was repeated for each slice generated from both the x-ray and gamma ray scans. In addition to the quantitative data, the information was also used to process Spectral (elemental) Graphs and Picture Plots. Spectral graphs are traverse concentration profiles of each element, showing the pattern of distribution through the tooth structure. Picture Plots are qualitative representations (maps) of relative concentrations, distributed across the scanned region, for each element.

4.3.5 Statistical Analysis

Statistical analysis using independent student t-tests was conducted to compare the crater lengths and depths of Fluoride vs No-Fluoride groups. There was an appropriate assumption of normality. A p-value of less than 0.01 was taken to indicate statistical significance.

In addition to the aforementioned statistics used to indicate significance for the crater length and depth measurements, elemental concentrations were also statistically analysed. SPSS Version 14 (Statistical package for social sciences, SPSS Inc., Chicago, Ill, USA.) software program was used. An analysis of variance (ANOVA) was conducted to examine the concentrations of elements (F, Mg, Na, Zn and Ca) and the factors included were Fluoride versus No-fluoride, Root Resorption Crater versus Normal Tooth Structure and Cementum versus Dentine. Significant interactions between factors were also included in these models. A multivariate ANOVA was used to examine the effects of these factors on the complete collection of elements as a whole.

The error of the measurement was calculated for F, Mg, Na, Ca and Zn and was based on triple measurements performed on Fluoride and No-fluoride randomly selected samples. An ANOVA was performed, using each group of repeated

measurements as a unit. The root mean square error was used to give the standard error of measurement. The coefficient of variation (CV) was also calculated from the standard error (SE) measure as a percentage of the mean.

Given the large number of dependent tests conducted, a p-value of less than 0.01 was taken to indicate statistical significance, while p-values between 0.01 and 0.05 were assigned “marginal” status.

4.4 Results

4.4.1 Crater Measurements

Depth and length measurements were taken of the root resorption craters, which were later subjected to NMP scanning. This crater represented the largest crater on the mesial surface (direction of the orthodontic force) of the mid-root region. When maximum depth and length measurements of Fluoride and No-fluoride groups were considered separately, the results demonstrated a highly significant difference ($p=0.001$) (Figures 9 and 10). The values for the root resorption craters in the No-Fluoride group had a mean length of $467.01 \mu\text{m}$ (± 192.94) and depth of $46.73 \mu\text{m}$ (± 5.96). The Fluoride group had significantly smaller craters in length and depth. Their mean length was $225.14 \mu\text{m}$ (± 51.13) and depth was $20.76 \mu\text{m}$ (± 2.78). The range of depth and length measurements was less in the fluoridated group. When the lengths and depths were considered together there was a marginally significant difference between the two groups ($p=0.055$). This may be due to the sample size and/or individual crater morphology. Therefore, the Fluoride group had significantly reduced lesion depth and length compared to the non-fluoridated group, but only when these measurements were considered separately.

4.4.2 Elemental Concentrations

The Fluoride and No-Fluoride groups were analysed for their elemental content. The error of the measurement was found to be minor (Table 1). The results for each tooth sample were divided for the purposes of evaluation into: root resorption crater cementum (representing the margin of the lesion), root resorption crater dentine (representing the surface of the crater floor and its immediate sub-surface layer), and the cementum & dentine of the adjacent tooth physically unaffected by resorption. Multivariate ANOVA analysis, taking the group of minerals as a whole, demonstrated significant differences between Fluoride/No-Fluoride ($p < 0.01$), Dentine/Cementum ($p < 0.01$), with a marginally significant interaction ($p = 0.01$). However, there were no significant differences between overall elemental concentrations in Root Resorption and Normal Tooth Structure ($p = 0.27$), although there was a marginal interaction between Fluoride/No-Fluoride and Root Resorption/Normal Tooth ($p = 0.027$). Essentially, the largest differences were between Fluoride/No-fluoride, followed by Dentine/Cementum.

When individual elements were assessed the Fluoride group had significantly more fluorine concentration in their cementum, compared to the No-fluoride group ($p < 0.01$) (Figure 11). Overall the Fluoride group had a greater concentration of fluorine (mean concentration 18661.04 ppm) compared with the No-Fluoride group (mean concentration 9791.25 ppm) (Table 2). However, both Fluoride and No-fluoride groups had a similar distribution pattern of fluorine through the teeth (Figure 12 and 13).

There was no significant difference between magnesium in any of the analysed groups (Figure 14). Whereas, sodium demonstrated significantly higher concentrations in the Fluoride group (mean concentration 1409.54 ppm, standard error 440.96) compared to the No-fluoride group (mean concentration 8232.04 ppm, standard error 440.96) ($p < 0.01$). There was significantly more sodium in dentine (mean concentration 12639.79 ppm) versus cementum (mean concentration 9633.79 ppm) ($p < 0.01$) (Figure 15). There were no other significant differences.

Aluminium had marginally significant increases in cementum (mean concentration 307.125 ppm, standard error 55.33) compared to dentine (mean

concentration 125.21 ppm) ($p < 0.05$). However, there were no other differences noted (Figure 16).

Zinc had marginally significantly greater concentration in the Fluoride group (mean concentration 270.29 ppm, standard error 16.06) compared to the No-fluoride group (mean concentration 174.04 ppm) ($p < 0.05$). The root resorption craters had more zinc in their dentine (mean concentration 207.92 ppm, standard error 22.72) compared to the non-root crater tooth structure (mean concentration 188.75 ppm) ($p < 0.01$) (see Figure 17).

Strontium had significantly higher concentrations in the dentine (mean concentration 244.58 ppm, standard error 7.93) of all the examined groups compared to cementum (mean concentration 194.79 ppm) ($p < 0.01$). There were no other significant differences for this element (Figure 18).

Calcium was found to be significantly higher in the dentine (mean concentration 37.97%, standard error 1.42) compared to cementum (mean concentration 23.71%) ($p < 0.01$). There was also a marginally significant difference between the No-fluoride (mean concentration 26.10%, standard error

1.42) and Fluoride groups (mean concentration 35.58%) ($p<0.05$) (Figure 19). The overall pattern of distribution of calcium in the Fluoride group was low superficially, which quickly peaked in the dentine. Whilst in the No-fluoride group there was a more gradual increase in cementum distribution (Figure 20 and 21).

An analysis of the total elemental concentrations demonstrated a significant difference between Fluoride & No-fluoride groups (Table 3) and dentine & cementum comparisons ($p<0.01$). However, the difference between root resorption crater tooth structure and normal tooth, also between the dentine and cementum of the Fluoride and No-Fluoride groups was marginally significant ($p<0.05$).

In summary, the Fluoride group overall had significantly altered cementum elemental content. These teeth had higher F, Zn and Na ($p<0.01$). Also, the root resorption craters of this group had significantly increased concentrations of F and Zn ($p<0.01$) and marginally significant increased Ca concentrations ($p<0.05$).

4.5 Discussion

4.5.1 Crater Size

A previous publication by Foo et al¹⁷ which examined volumetric size of OIRR craters of rats exposed to fluoridated water was only able to establish a non-significant trend towards smaller craters. The present study used a different approach to measure the dimensions of selected craters. There was a significant difference demonstrated when length and depth of the root resorption craters were considered separately. However, similar to the aforementioned study, when considered together, only a marginal significance was demonstrated. This finding may be in part due to the limited sample sizes in both these studies.

Alternatively, a possible explanation for the significant difference in length and depth of craters may be the effect fluoride has on osteoclast attachment and resorption patterns. Taylor et al²⁴ examined the effects of fluoride on osteoclasts and found that resultant lacunae were longer, but shallower. This pattern of resorption may be implicated to support the notion that the OIRR craters on cementum in samples of the fluoride group were of an altered morphology, in addition to having altered size. Therefore, this may be a reason why the values were significant when considered separately, but not as mean

volumes. Thus, fluoride may affect the shape, extent and severity of root resorption craters.

The present finding also has implications for research studying root resorption craters, as length and depth may need to be considered separately. Using mean volumes may mask the true extent of resorption.

4.5.2 Element Distributions

Overall there was only a marginally significant difference between the Fluoride/No-Fluoride groups and the elemental concentration of root resorption craters and normal tooth structure. This may be due to the ability for cementum to resist root resorption to a limited degree.²⁵

Resorption is usually followed by remineralization. A dynamic exchange of minerals occurs superficially and this limits the extent of more minor resorptive defects. Subjacent unaffected tissue provides a reservoir for diffuse transition of elements.²⁶ The minerals in the circulating fluid can also react with cementum. A relative time-frame for re-mineralisation can be extrapolated from that measured for fluorine, which is incorporated into enamel, occurs within one hour from the microcirculation.²⁷ When the root surface is breached, repair

matrices become attached to the resorbed surface.²⁸ Following the detachment of odontoclasts the cementogenic cells re-populate. This is followed by electron-dense globular accumulations indicating re-mineralisation. This biomineralisation process together with a new paradigm has been more recently established suggesting fluoride is an active participant in the precipitation process and nature of biogenic apatites.²⁹ The role of fluoride was suggested as being vital in calcium phosphate formation for teeth *in vivo*, effecting both the process and characteristic of the final products. Fluoride was seen to accelerate the hydrolysis of acidic precursors and increase apatite growth rates via precipitation.²⁹ The present study supports the proposal that cementum has inherent abilities to resist resorption. Furthermore, this may mean that pre-treatment cementum quality impacts on the ability for tooth roots to resist damage, as the outcome of root resorption reflects the original mineral concentration. Secondly, that the presence of fluorine may increase "repair" (or limit destruction) by being an active participant in accelerating calcium phosphate precipitation. Therefore, fluoride may be extrapolated as a potential preventive agent in limiting the extent of orthodontically induced root resorption craters.

Fluorine concentration in teeth has been previously shown to reflect environmental exposure to this mineral.³⁰ There was a significantly increased fluorine concentration in the cementum of rats that were experimentally

exposed to fluorine (Figure 22 and 23). This may also demonstrate that short-term exposure, during the experimental period of two-weeks, to fluoridated drinking water was already reflected within the tooth root structure. This is in agreement with the concept that minerals in the circulating fluid can react with cementum. In particular the fluoride ion reacts aggressively with hydroxyapatite.³¹ Therefore, it is expected that fluorine reaches tooth roots in patients who are exposed to systemic fluoride. This may have clinical implications since it would not only be the history of fluoride intake, but also exposure during orthodontic treatment, which may influence the dynamic exchange of elements at the cementum interface, and subsequently root resorption.

When comparing the root resorption crater dentine, both Fluoride and No-Fluoride groups had less fluorine concentration compared to 'normal' dentine. A similar pattern was found in the cementum. This means that root resorption craters have reduced fluorine concentrations. However, in the Fluoride group the concentrations of fluorine remained significantly higher than the group not exposed to fluoridated water. Mineral dissolution is said to occur as a result of the OIIRR process and may have caused this general reduction in fluorine concentration at the periphery and in the depths of the lesions.³¹

In contrast to this loss of fluorine associated with root resorption craters, magnesium maintained its concentration between and within the groups. This is in disagreement with a previous study looking at overall mineral concentrations of cat teeth exposed to resorptive pathology.³² However, the present study's finding that magnesium is maintained within the local region may relate to the cementum's role as a dynamic interface. Magnesium is present in the hydroxyapatite lattice and has been suggested to be important in contributing to cementum mineralisation and plays a role in controlling hydroxyapatite crystal growth.³³ The finding that magnesium is similar in both the root resorption craters and normal tooth structure may mean that this element is able to resist the process of dissolution better than the elements that fall in concentration.

Unlike the elements that were maintained or reduced in concentration in root craters, zinc actually increased. Zinc was present in higher concentrations in the deeper parts of the craters and in the group exposed to fluoridated water (Figure 24 and 25). Like magnesium, the presence of zinc may be an important contributor to the ability for teeth to resist OIRR.

Zinc may play a vital role in the dynamic processes affecting cementum. Modulation of osteoclastic resorption of bone and dental tissue in the presence of zinc has been examined.³⁴ It was established that the lacunae developed on

tooth cementum, in the presence of extracellular zinc, were fewer in number and had smaller surface areas.

Sodium was higher in dentine and in the fluoridated group. An increase in sodium for the Fluoride group could be attributed to the sodium fluoride in their drinking water. In contrast the root resorption craters did not have a significantly greater concentration of sodium. This is in disagreement with a study which looked at overall mineral concentrations in root resorption lesions in cats, and found that the teeth with resorption craters had higher concentrations of sodium.³² However, the significance of sodium concentration has not previously been examined in relation to root resorption.

In contrast to sodium, calcium was in lower concentration within the root resorption craters, but followed the same pattern of distribution – having higher concentration in dentine compared to the cementum.³⁵ Of note is the maintenance of higher concentrations of calcium in all parts of the teeth in the rat sample exposed to systemic fluorine. This may relate to the finding that teeth exposed to fluoride have smaller OIIRR craters and are thus inferred to be more resistant to root resorption.¹⁷

Aluminium and strontium were present in higher concentrations in cementum. Unlike previous studies that suggest a relationship in the uptake of strontium, zinc and fluorine,³⁶ the present study did not demonstrate such trends.

There is conflicting evidence of the effect strontium has on cementum solubility. An increased presence of strontium has been shown to increase cementum and enamel solubility.^{37,38} However, it has also been shown to decrease solubility when administered in the presence of fluoride.³⁶ Hydroxyapatite can reduce in solubility by up to 50%.³⁸ Like zinc, strontium is another element which has been related to reducing bone resorption.³⁹ However, implications of this for root resorption are unknown.

Ideally, the morphology and mineral content of OIIRR craters should be studied in three-dimensions without the need to prepare the samples. The use of NMP machines must meet the condition for a flat polished surface for reliable data to be generated. Thus, only one crater per tooth could be examined. The choice of using the largest mid-root crater on the surface exposed to the direction of the force (mesial root surface) was intended to maximise the representation and ensure greater consistency of the samples. Mid-root minerals have been suggested to reflect on average the entire tooth root,⁴⁰ whilst the location of craters at sites of compression have been shown to be associated with root resorption lesions.⁴¹ Such issues may be addressed with the development of

future technologies. Nevertheless, with current limitations this study was able to demonstrate the elemental distribution and concentrations in OIIR craters.

4.6 Conclusions

1. Elemental distribution across root resorption craters was demonstrated successfully with the developed methodology.
2. Overall tooth root structure seemed to resistant major alterations to its pattern of elemental distribution as a result of the OIIRR process.
3. OIIRR craters of the group exposed to systemic fluoride had reduced lengths and depths, possibly due to altered shape and size.
4. Systemic fluoride intake was associated with increased concentrations of fluorine and zinc, which may have contributed to a trend towards maintenance of higher calcium concentrations within these root resorption lesions.
5. Pre-treatment cementum quality and systemic fluoride during orthodontic force application may influence the extent and severity of root resorption defects.

5.1 Abstract

Introduction: Cementum is the interface of the tooth's response to orthodontic induced inflammatory root resorption. Study of cementum structure following orthodontic force may help to increase our understanding of the resorptive process and the potential role elements may have in its prevention.

The aim of this study was to conduct an analysis of the elemental composition of human root cementum, following heavy and light orthodontic force using the Commonwealth Scientific and Industrial Research Organisation and Australian Research Council's National Key for Geochemical Evolution and Metallogeny of Continents Nuclear Microprobe (CSIRO-GEMOC NMP). Furthermore, a methodology was established for this machine, enabling more accurate readings of cementum than previously published from tooth root samples that could remain relatively unaltered for the scanning process.

Method: Four teeth, which met inclusion criteria, were analysed. Buccal directed force of 25 g (light) and 225 g (heavy) were imparted by 0.016" and 0.017 x 0.025" beta-titanium-molybdenum alloy springs, respectively. The left teeth were designated experimental teeth and their contralateral teeth served as controls. Following the experimental period of 4.1 weeks,

the teeth were extracted. Samples were sectioned longitudinally, embedded in epoxy resin, polished and prepared for analysis by the CSIRO-GEMOC NMP. Six pre-determined dentine-cementum points per tooth (800 x 800 μm) were analysed and deconstructed using the Geo-PIXE II™ Version 3.8 Program.

Results: The CSIRO-GEMOC NMP was able to detect fluorine, magnesium, sodium, calcium, iron, zinc and strontium. General trends for these elements support those of previous studies. However, there was marked inter-individual variation for absolute concentrations. Orthodontic force below 250 g did not appear to consistently alter the pattern of cementum elemental distribution. However, there was a significant reduction of overall zinc & fluorine, and a marginally significant reduction in strontium, concentrations comparing heavy and light force with controls ($p < 0.01$).

Conclusion: Findings indicate that cementum may have the capacity to resist significant element alterations. However, the reduction in Zn and F following exposure to orthodontic force may have implications for subsequent root resorption.

5.2 Introduction

Orthodontically Induced Inflammatory Root Resorption (OIIRR)¹ refers to root resorption resulting from orthodontic treatment. OIIRR is an unpredictable adverse effect involving transient inflammatory surface resorption. The exact mechanism of OIIRR is unknown. The severity of the outcome of this process may be related to the orthodontic force level imparted on the tooth.² Cementum is an integral part of this process. Understanding its structure may help to elucidate more information regarding its role in protecting teeth and its ability to normally resist resorption.

Cementum is an important dynamic interface between the tooth and the periodontal environment. Similar to other hard tissues, hydroxyapatite in cementum is not pure, and contains elements from its microenvironment.³

Trace elements are present in cementum. Manganese has been reported to be present at 0.5-1.4% wt.⁴⁻⁷ The cementum fluoride concentration was shown to be inversely proportional to magnesium.⁸

Previous studies have detected citrate in cementum at a concentration of $0.86 \pm 0.06\%$ wt.⁹ Carbonate was also present at 2.79% wt and for both these elements there was no inverse relationship with fluoride, unlike that

observed in enamel.⁹ Concentration of sodium has been estimated at 0.3%.⁵ Zinc and strontium have also been noted in tooth roots.^{10,11} Strontium, like fluorine, is an agent used by the dental profession in topical applications on tooth surfaces.¹¹

Fluoride has a varied distribution through and across the tooth. Its concentration depends on age and environmental fluoride exposure. In general, there is an increase with age and ingestion of fluoridated water.^{4,9} The fluoride concentration has been estimated to average 45-65% ash weight. In human teeth an increasing gradient from inner to the outer surface of tooth roots has been demonstrated.¹²

Quantitative assessment of calcium, phosphorus and fluoride concentrations have indicated a reduction of mineral concentration towards the apex.¹² There was no difference between buccal and lingual surfaces, except for increased fluoride bucco-cervically. There were significant differences between the upper half of the root compared to the apical part. However, the distribution of minerals within mature root tissue shows a great variability.³

Orthodontic force and its relationship to cementum minerals has previously been examined. Rex and co-workers¹³ used an electron microprobe technique to study the effects of light (25 g) and heavy (225 g) force. Following light force, there was no apparent alteration in tooth mineral

composition. However, a reduction in elemental concentration was demonstrated following increased orthodontic force. Heavier forces resulted in more marked changes. There was an increase in calcium and phosphate in areas of compression, and a reduction in calcium in areas of tension. In contrast fluoride was inversely related to calcium and phosphate changes. With regards to fluoride, however, overall there was no significant difference between light, heavy or control teeth.

Various explanations have been used to support the trend of altered mineral content with orthodontic force, including:

1. pH changes in microenvironment:^{14,15} the inflammatory process involved in tooth movement results in the local drop in pH level, which could lead to dissolution of mineral content of the tooth root surface.
2. Cell mediated response:¹³ lowering the pH of tissues results in increased activity of osteoclasts whilst inhibiting osteoblasts.¹⁶ This mechanism may have a similar effect on odontoclasts and odontoblasts
3. Homeostasis:¹⁷ osteoblasts activate calcium channels, which lead to an increase in intracellular calcium, resulting in hypocalcemia. Physiologic processes then act to restore balance. In support, hypocalcaemic states in rats have been associated with an increased

severity of root resorption.¹⁸ In contrast, Goldie and King¹⁹ did not demonstrate the same findings.

Thus the mineral content presented by a tooth could reflect the dissolution of crystallites due to the resorptive process. However, it could also represent subsequent repair mechanisms. This is because the resorptive process could be countered by remineralization. A dynamic exchange of elements may occur superficially limiting the extent of more minor resorptive defects. Subjacent unaffected tissue could also provide a reservoir for diffuse transition of elements.³

There are various methods to study elemental composition of teeth. The nuclear microprobe employs Proton Induced X-ray Emissions (PIXE) and Proton Induced γ -ray Emissions (PIGE), which allows mapping of multiple trace elements at micron (μm) resolutions. Compared to other available techniques, the Commonwealth Scientific and Industrial Research Organisation and Australian Research Council's National Key for Geochemical Evolution and Metallogeny of Continents Nuclear Microprobe (CSIRO-GEMOC NMP) provides a powerful combination of element spatial (resolution of 1-2 μm) and quantitative analysis. This technology has not previously been employed to study tooth root elements in the context proposed.

The NMP is a non-destructive analysis with regards to both the beam itself and the method by which samples need to be prepared. The beam deposits little energy over the first 30 μm of sample penetration. Furthermore, the sample requires minimal preparation compared to other techniques.^{20,21} This means fewer potential disturbances to the elemental content of the sample. However, a condition for NMPs is a flat surface for scanning to maximise reliability of x-ray and gamma ray detection.²² Therefore, samples lacking smooth surfaces require sectioning. This technology is not suitable for bulk sample analysis, but the data gathered is respected for its high quality.

The aim of this study was to analyse the elemental composition of superficial human tooth root structure following heavy and light orthodontic force using the CSIRO-GEMOC NMP. Furthermore, a methodology was established for this machine, enabling detailed quantitative and qualitative readings.

5.3 Materials and Methods

5.3.1 Sample

Subject one (S1) was a 13.5 year old female. The second subject (S2) was a 15.1 year old male. Maxillary first premolar teeth from these individuals were used, thus a total of four teeth were analysed for this section (Ethics Committee of the Central Sydney Area Health Service and CSAHS Human Ethics Review Committee, United Dental Hospital, Sydney, Australia, Project: 5/98). The samples met the following inclusion criteria:²³

1. Bilateral maxillary first premolar teeth to be extracted for orthodontic purposes
2. Complete apexification
3. No history of trauma, dental restorations, pathology or developmental abnormalities
4. No history of bruxism
5. No medical history that may affect dental development
6. Knowledge of birth place and residence to present
7. Knowledge of fluoride consumption history

The subjects were born and resided in Sydney, Australia where the water supply is fluoridated to 1.0 ppm. They were both exposed to topical fluoride

in the form of dentifrice and occasional professional application. Water consumed was through mains tap water.

The health of these teeth was determined clinically and radiographically with a long-cone paralleling technique.

5.3.2 Clinical Procedure

The maxillary left first premolar tooth of S1, received the light force. A 25 g buccally directed force was applied to the tooth using a 0.016" beta-titanium-molybdenum alloy (TMA[®]) (Ormco, CA) spring (tooth designated L7). The heavy force applied to the maxillary left first premolar tooth of S2, had 225 g buccally directed force applied by a 0.017" x 0.025" TMA[®] (Ormco, CA) spring (tooth designated H17). These springs consisted of an activated segment of archwire, engaged in 0.022" SPEED brackets (Strite Industries, Canada) bonded to the first permanent molar and the experimental tooth (Figure 1). The right contralateral teeth served as a control and had SPEED brackets bonded to them (S1 control designated L8 and S2 control designated H18). The force magnitude was measured to the nearest gram using a strain gauge (Dentaurum, Germany). Glass ionomer cement (Transbond, 3M UnitekTM) was bonded on the occlusal surfaces of the lower first molar teeth to minimise occlusal trauma to the maxillary first premolars during the experimental period.²⁴ After 4.1 weeks the upper first

premolar teeth of the subjects were extracted. Instructions were given to the oral surgeons to avoid forceps contact on and apical to the cervical cementum. The teeth were stored in 5 ml of Milli-Q[®] and then underwent ultrasonic cleaning for 10 minutes to remove remaining periodontal ligament and biological debris.²⁵ The teeth were then disinfected in 70% alcohol for 30 minutes and stored in Milli-Q[®] at ambient room temperature ($23^{\circ} \pm 1^{\circ}$).²¹

5.3.3 Sample preparation

Part of the crown of the sample teeth was removed using a high-speed diamond bur and Milli-Q[®] irrigation. Following seven days of air-drying, the teeth were embedded in epoxy resin [Procure 812 (ProSci Tech, Qld, Australia), Nadic Methyl Anhydride (NMA) (ProSci Tech, Qld, Australia) and Benzyldimethylamine (BDMA) (Probing and Structure, Qld, Australia) in ratio of 2.7:2.3:1, respectively]. These were then oven cured for 24 hours at 60°. The teeth were then sectioned longitudinally from a buccal-lingual direction, using a diamond blade (Leco, MI, USA) mounted on an Accutom (Struers, Denmark).

Polishing was then performed manually on a DP-U2 polishing machine (Struers, Denmark). The sandpaper grit used was P400 followed by P1200 (Leco, MI, USA). A final polish was achieved on an 8" diameter, 203 mm

PAN W PSA polishing disc (Leco, MI, USA) with 6 μm water based polycrystalline diamond suspension (Allied High Tech Products Inc., CA, USA). Following satisfactory polishing, as assessed under light microscope, a second section was made 0.5 cm from the first cut to achieve flat parallel surfaces. These were then mounted on metal stubs using carbon sticky paper. Carbon dag was then added and the sample carbon coated.¹² The Nuclear Microprobe machine developed by the Commonwealth Scientific and Industrial Research Organisation (CSIRO) and the Australian Research Council's National Key for Geochemical Evolution and Metallogeny of Continents (GEMOC) (Melbourne, Victoria, Australia) was then used for analysis.

5.3.4 Sample Analysis

5.3.4.1 NMP

The spatial distribution of multiple elements was measured at six pre-determined dentine-cementum points per tooth (Figure 2). Spot scanning of 800 μm x 800 μm areas was conducted, on the buccal and lingual, at designated cervical (cemento-enamel junction), middle (mid-point taken as half-way between the apical and cervical areas scanned) and apical (area taken coronal from a perpendicular at the level of the tooth apex either side

of the apical foramen) regions (Figure 2). The analysis was performed with 3.0 MeV protons and the beam focused at $1 \times 1.8 \mu\text{m}^2$. The beam current was maintained at 4 nA. An aluminium absorber of 100 μm used between target and Germanium (Ge) detector (Canberra Ultra-Ge Detector[®]). The elements detectable under gamma rays were sodium (Na), fluorine (F), magnesium (Mg), boron (B), aluminium (Al) and silicon (Si). Whilst under x-rays calcium (Ca), iron (Fe), nickel (Ni), copper (Cu), zinc (Zn), bromine (Br), rubidium (Rb), strontium (Sr), tin (Sn), barium (Ba) and lead (Pb) were measurable.

5.3.4.2 Spectral Deconvolution of Element Spectral Distribution Maps

Geo-PIXE II[™] Version 3.8 Computer Program was used to extract and translate the data.²⁶ This program provided the tools for manual analysis of regions by a program function that allowed “shapes” to be drawn over the downloaded scanned image. These shapes calculated multiple scanned points producing average readings of the concentration of each element. Overall element distribution was determined by taking a “traverse outline” perpendicular to the edge of the image, marking the outer surface of the cementum and drawn for maximum coverage of the scan. Element concentration in dentine was assessed using the “circle” function to cover

the region, whilst for cementum the “box” function was used to overlie as much of this structure as possible, thereby improving the counting statistics. Information generated from this Program’s functions included average concentrations of 500 plus readings per extracted region drawn and minimum detection limits (MDL) for the presence of elements. This was repeated for each slice generated from both the x-ray (PIXE) and gamma ray (PIGE) scans. In addition to the quantitative data, the information was also used to process Spectral (elemental) Graphs and Picture Plots. Spectral graphs are traverse concentration profiles of each element, showing the pattern of distribution through the tooth structure. Picture Plots are qualitative representations (maps) of relative concentrations, distributed across the scanned region, for each element.

5.3.5 Statistical Analysis

In addition to the analysis generated by the Geo-PIXE II™ 3.8 Computer Program,²² differences between the overall dentine and cementum of heavy, light and control groups were further tested statistically.

An analysis of variance (ANOVA) was conducted for each element of interest (F, Mg, Na, Ca, Fe, Zn and Sr) using the following factors: force (control, heavy, light), surface (buccal, lingual), height (apical, middle, cementoenamel junction (CEJ)) and type (cementum, dentine). In each case

the accuracy of each of the multiple readings, done by the Geo-PIXE II™ software, of which the averages contribute toward a single value at a particular point that the machine measures, is assumed for statistical purposes. MINITAB® Version 14 statistical program was used. Bonferroni adjustments were conducted where appropriate. A p-value of less than 0.01 was taken to indicate statistical significance. P-values of less than 0.05 were considered marginally significant.

In addition, z-scores were calculated using the mean overall concentrations and their standard deviations for the purposes of making comparisons between heavy/light, heavy/heavy-control and light/light-control. This was done using the Excel (Microsoft® Office 2000) software program. The concentrations were considered equivalent to population-values, as there were over 500 measurements at each point. A p-value of less than 0.01 was taken to indicate statistical significance.

5.4 Results

1. Fluorine

Overall fluorine concentration ranged from 10149 ppm to 97184 ppm in the cementum. In the dentine the levels ranged from 2165 ppm to 19063 ppm. Fluorine followed the same trend in all teeth sampled its greatest concentration at the superficial cementum surface, then dropping sharply to lower levels in the dentine, towards the pulp (Spectral Graphs in Figures 3 to 9). Overall, fluorine was found to be significantly higher in the cementum compared to dentine ($p < 0.01$) (Figure 10).

There was only a marginally significant difference overall between buccal/lingual surfaces ($p < 0.05$). However, the samples did demonstrate individual differences. The heavy force group on the buccal had the highest cementum fluorine concentration at the apex and least at the CEJ – 94331 ppm to 67107 ppm (Table 1). The dentine on this side also demonstrated a decreasing trend, with the apex having the highest (4529 ppm) and the CEJ having the lowest (2604 ppm) concentrations (Table 2). In contrast, the lingual surface had a peak concentration in its middle third for both the cementum and dentine (78227 ppm and 2416 ppm, respectively).

In the cementum of the light force sample there was a low fluorine concentration lingually at the CEJ (43353 ppm) and a high value apically (55104 ppm), following the trend of the heavy force sample (Table 3). However, in contrast the buccal apical cementum had a lower concentration (7730 ppm) compared to the CEJ (52182 ppm). This was not seen in the dentine which followed the trend of the heavy force sample, generally having an increasing concentration from coronal to apical (Table 4).

The control teeth had marked individual variation, most strikingly in the apical dentine. There was a higher concentration in the light force control (lingual 19063 ppm and buccal 17243 ppm) and much less in the heavy force control (lingual 2982 ppm and buccal 3402 ppm) (Table 2 and 4). The heavy sample control had higher apical fluorine compared to the CEJ, but peaked in the middle cementum on the lingual side (93632 ppm). This was not reflected in the underlying dentine, which had its lowest lingual dentine concentration in the middle third (2873 ppm). A low concentration in the middle cementum was also present on the buccal side (2493 ppm).

The light force control also demonstrated the same trend as all the other samples of having higher apical and coronal values for both cementum and dentine. Once again, the middle third revealed concentrations,

which were in contradistinction to the establishing trends. The middle cementum on the buccal side had a concentration of 82290 ppm, following the reducing gradient from apical to CEJ regions (apical 93135 and CEJ 80675 ppm). Dentine on both surfaces also followed the high to low, apical-coronal, trend.

Comparison of teeth exposed to the orthodontic force compared to the controls revealed significant differences. Overall fluorine concentration was greatest for the control groups (42300 ppm), followed by heavy (38400 ppm) and the light force (2600 ppm) samples ($p < 0.01$).

When the heavy force sample was compared to its contralateral tooth control the greatest differential was found in the buccal mid-third cementum (z-difference -39.25 , $p = 0.00$). Other noticeable differences included a reduced mineral concentration in the heavy force group at the buccal cervical cementum and the lingual apical cementum when compared to the control ($p = 0.00$). Similar to the comparison between light and heavy forces, the heavy compared to its control demonstrated least difference in the lingual CEJ dentine (z-difference 0.89 , $p = 0.19$) and the lingual mid-third dentine (z-difference 1.85 , $p = 0.03$).

The light force sample contrasted its contralateral tooth control and the largest difference (z-score -80.37) was in the lingual middle-third

cementum ($p = 0.00$). The least difference was at the lingual mid-third dentine (z-difference 1.85, $p=0.03$). This was also seen when comparing the heavy group and its control.

Therefore, in general the fluorine distribution peaked in the cementum and declined sharply to a low consistent level through the dentine. There were high fluorine readings apically and at the CEJ. Mixed readings were measured for the middle areas.

There was a significant difference in fluorine concentration for light, heavy and control groups. Both heavy and light forces having reduced fluorine. Light force having the lowest concentration compared with the controls.

2. Magnesium

Overall the magnesium concentration in cementum ranged from 1795 ppm to 180 ppm (Table 1 and 3). For dentine its highest value was 2486 ppm and lowest was 521 ppm (Table 2 and 4). Spectral distributions showed a general trend of gradual increase in magnesium concentration from the outer surface, increasing toward the pulp. It is also notable that a marked rise occurred at the cemento-dentinal junction. This then marked a point where the concentration began to fluctuate markedly (Figures 3 to 9).

Magnesium demonstrated marginally significant differences between the apical, middle and cervical regions of the teeth ($p=0.04$) (Figure 11). However, in general the majority of areas on the teeth exposed to force showed insignificant differences with their contralateral controls. The heavy sample showed similarity with its control at the lingual cervical and middle, dentine and cementum regions ($p>0.05$). Both the heavy and the light group and their respective controls did not have significant difference at the buccal cervical cementum.

Therefore, the majority of comparisons demonstrated insignificant or only marginal significance between the groups.

3. Sodium

Sodium in cementum ranged from a low of 4613 ppm to 16889 ppm. In the dentine a concentration of 8271 ppm to 20636 ppm was noted (Tables 1 to 4). The spectral graphs showed that low concentrations were found in the cementum. This was followed by a gradual increase, then a plateau in the dentine, which was maintained. Higher concentrations were noted away from the superficial surfaces, in dentine. Compared to the other trace elements, sodium demonstrated more consistent trends (Figures 3 to 9).

Going from apical to coronal, the majority of surfaces examined had a sodium concentration that peaked in the middle-third of the tooth. This low-high-low trend from apical-middle-CEJ, respectively, occurred in all but the cementum in the lingual of the light and heavy force controls, and in the dentine of the heavy force control.

Comparison between the groups demonstrated significant differences in sodium concentration of the cementum (8400 ppm) and dentine (13500 ppm) ($p < 0.001$) (Figure 12). Furthermore, the mid-third of the teeth had higher concentrations compared to the apex and cervical regions ($p < 0.001$). There was a marginally significant difference between control/heavy/light force groups ($p = 0.04$).

4. Calcium

Generally calcium concentration rose in the cementum and steadied, often with a slight drop at the dentine-cementum junction heading toward the pulp. However, in the apical spectral plots it is evident that the increase in concentration of cementum is more gradual (Figure 13). The concentration range of cementum calcium was 12.4% to 41.4%. For dentine the range was 26.2% to 45.1% (Tables 1 to 4).

Overall calcium was significantly higher in the dentine (34.0%) compared with the cementum (21.5%) ($p < 0.001$). There was a

marginally significant difference between the apical/middle/cervical regions ($p=0.011$) (Figure 14). There were no significant differences found between controls/heavy/light forces.

Higher values were noted in the CEJ regions compared to the apex, although the majority of differences were minor. Most surfaces showed a peak concentration at the CEJ and a gradual reduction to the middle then apical thirds. The exceptions were the lingual of the heavy control and the lingual cementum of the light force and light control groups, which had a reduced concentration in the middle-thirds. In direct contrast, the lingual cementum of the heavy force, the buccal surface of the light force and the dentine of the light force control on both surfaces had slightly higher concentrations of calcium in their middle thirds (Tables 1 to 4).

When comparing the samples to each other most of the differences were insignificant. Therefore, calcium was relatively similar for all parts of the tooth and between samples, except for increased variability towards the apex.

5. Iron

Iron was not present in the cementum above the detection limit in some cases (Tables 1 to 4). There was marked individual variability in the

presence of iron. Although cementum demonstrated significantly higher concentrations compared with dentine ($p<0.001$) (Figure 15).

6. Zinc

Zinc followed a similar trend in all samples. That is, there was a peak in the cementum followed by fall in the dentine. The only exception was the more gradual decline towards the pulp in the apical regions. Comparison of cementum and dentine demonstrated a significant difference ($p<0.001$). The range of zinc varied in the cementum from 515 ppm to 1157 ppm, in the dentine the range was 49 ppm to 860 ppm (Table 1 to 4).

A high concentration at the apex compared to the CEJ was the most common trend found in all samples. This was significantly different when comparing middle and cervical regions ($p<0.01$) (Figure 16). The opposite (low concentration at the apex) was only seen in the buccal control light force cementum (Table 3).

Therefore, a generalised trend was observed for a high to low gradient for zinc concentration superficially to deeper surfaces and apically towards the crown of the tooth.

When comparing force and controls a significant difference was noted ($p=0.002$) with light and heavy forces having reduced concentrations. Zinc concentrations were lower in the light force group compared to heavy force group.

7. Strontium

Strontium followed a distribution across the cementum and through the dentine similar to that of zinc – peak concentration in cementum followed by a decline to a low level in the dentine (Spectral Plots Figure 13).

The concentration of strontium comparing buccal and lingual surfaces showed a tendency for the buccal surface to have a lower concentration. There was a general trend of higher strontium in cementum compared to dentine, but this was not significant.

Overall, there was a marginally significant difference between control/heavy/light force groups ($p=0.02$) (Figure 17). The force groups having reduced concentrations of strontium compared to the controls. With consideration to apical and coronal concentrations, the heavy and light force cementum groups were in contradistinction. Light force had low lingual apical concentrations whilst the buccal contralateral surface had a higher concentration compared to the cervical regions. This was

opposite for heavy force. However, the dentine of these groups was in agreement – reduced buccal apical concentrations (Table 1 and 4). Also in agreement were the high apical concentrations between cementum of the heavy and light control groups.

8. Comparison of elements

All the samples had individual variations in concentrations of all elements. The overall mineral distributions were similar for zinc and strontium. This is seen in the spectral graphs, where the pattern of a rise in cementum followed by a fall to low levels towards the pulp, are almost identical (see spectral plots in Figure 13). In contrast, sodium had higher concentrations in the deeper layers. Magnesium also had high concentrations away from the superficial surface – the concentration was maximal at the cementodentinal junction. Fluorine had its highest concentrations on the outer cementum (Figures 3 to 9).

In summary, there was an overall significant reduction of fluorine and zinc, with a marginally significant reduction of strontium, when comparing force groups with controls ($p < 0.01$). However, there were no consistent site-specific areas of reduced concentrations.

5.5 Discussion

1. Fluorine

Previous studies have generally reported fluorine levels ranging from 0.15-0.9% wt.^{4,9} These studies used ash weight which would actually correspond to even lower values when converted to dry weight.²⁷ Nevertheless higher values have been reported with fluorine levels reaching 90000 ppm in the cementum.²⁷ In the present study, fluorine ranged from 10149 ppm to 97184 ppm in the cementum. Factors that may have contributed to the higher fluorine levels observed include increased sensitivity of the detection method and the regions analysed.

With typical proton energies of 3 MeV, the NMP is particularly sensitive to lighter elements such as fluorine which have pronounced gamma ray yields at these energies.²² Thus it may be reasonable to expect higher levels would be recorded compared to previous studies, especially studies that used techniques requiring bulk dissolution and destruction of samples.²⁸

Another factor contributing to the higher levels is that only a superficial area of 800 x 800 μm was analysed. It has been consistently reported that fluorine is present in higher concentrations towards the outer cementum.¹²

Recording of occasional high values towards the apex, not only in the cementum but also in the dentine, may be due to microprobe machine limitations. Analysing a non-uniform structure means that as the sample thins down, for example at a tooth's apex, the proton beam – which penetrates 60 μm into the sample – may reach the opposing surface (Figure 18). In teeth this means that the results could be skewed towards higher values where dentine readings may include minerals present in underlying cementum. However, in general the results reflect previous studies^{12,13} which indicate a trend towards greater fluorine on the buccal cervical parts of the root surface.

In terms of elemental content alteration as a result of teeth being exposed to orthodontic forces, there was a tendency for reduced fluorine concentration when comparing heavy force and its control, in areas of compression – buccal-cervical and apical-lingual areas. This was anticipated by a previous study but not demonstrated.¹³ However, no definitive picture emerged in the present study. Even though a significant difference was found between the groups overall (controls having the highest fluorine concentrations), which may reflect a demineralisation process, when specific regions of the teeth were examined no consistent trends emerged. This is supported by Rex et al¹³ where no significant difference in fluorine concentration was found when comparing heavy and light force groups to their controls. This

finding was rationalised by the belief that fluorine does not play an important role in the phenomenon of tooth movement and that there are large inter-individual variations in fluorine content.

An alternate explanation for this lack of a distinct mineral pattern is that fluorine remineralises rapidly. Enamel remineralization occurs within one hour from the microcirculation,²⁹ this may be extrapolated to cementum. Furthermore, fluorine can also re-incorporate into tooth structure without leaving the microenvironment of the remodeling unit.³⁰

2. Magnesium

Overall trends supported previously published work suggesting the concentration of magnesium is lower at the surface compared to deeper layers.^{5,27} Values reported ranged from 5000 ppm to 9000 ppm,²⁷ to higher values of 13000 ppm to 14000 ppm in an electron microprobe analysis.⁷ The present study found concentrations in dentine of 521 ppm to 2486 ppm, whilst in the cementum values were lower and ranged from 180 ppm to 1795 ppm.

Peak concentrations of magnesium increased from the CEJ to the middle-third, however more often there was a decline at the apex. However, overall these trends were marginally significant. Previous studies demonstrate a concentration gradient which increases from the

cervical region to apex.⁴ An explanation is that this may be due to the NMP gamma-ray penetration – at the apical end of the tooth the beam would possibly include a greater amount of cementum, beyond the dentine. It could be anticipated that if it were possible to limit the NMP beam depth to record dentine only, the concentration of magnesium at the apex would have been consistently higher.

Magnesium is present in the hydroxyapatite crystal lattice. It has been suggested that this element could be important in contributing to cementum mineralisation and may play a role in controlling the growth of hydroxyapatite crystals.⁷ Like previous work magnesium was found to be present in similar concentrations to calcium.³ In contrast, to reports that fluoride concentration is inversely proportional to magnesium⁸ no such clear relationship was seen in this study.

In terms of the effect of force, when both the light and heavy force groups were compared to their controls, the main differences noted were in the lingual apical regions. Arguments have been put forward in support of anticipated alteration in mineral content with orthodontic force. These include changes in the microenvironment which result from the cell mediated response to force. The inflammatory process involved in tooth movement results in the local drop in pH level, which could lead to dissolution of mineral content of the tooth root surface.^{14,15} The

cell mediated response results in increased activity of osteoclasts whilst inhibiting osteoblasts.¹⁶ This mechanism may have a similar effect on odontoclasts and odontoblasts.¹³ However, it should be noted that the differences in magnesium seen in the present study, between the groups exposed to force and the controls, were relatively small. Furthermore, when the groups were analysed there was no significant difference in magnesium concentration between force levels and controls.

3. Sodium

Sodium has been reported to be present at 0.3%.⁵ Electron microprobe analysis has reported higher sodium at concentrations of 0.8%.⁷ This is comparable to the present findings.

This study showed there were significantly higher sodium concentrations in the middle-third of the teeth and in the cementum. The finding that both sodium and fluorine are present in high concentrations in the cementum could have implications for root resorption. Sodium fluoride (0.5 to 1.0 mM) has been shown to reduce resorption lacunae and resorption areas of osteoclasts.³⁰

4. Calcium

The concentration of calcium demonstrated can be related to previous studies. Calcium has been reported to range from 24.0% to 29.24% dry weight as a mean total.^{6,31,32} Percentage ash ranges from 35.6% to 42.4%.⁴ The mean percentage weight concentration has been shown to vary between root and region of root surface – buccal-cervical 30.05%, buccal-middle 28.63%, buccal-apical 27.16%, lingual-cervical 29.69%, lingual-middle 28.90% and lingual apical 26.96%.²³

However, another study, which used electron microprobe analysis, reported very different results.⁷ A calcium/phosphate ratio of 1.8-2.2% was recorded at the cemento-enamel junction, 1.65% at the coronal third, 1.3% at the furcation and 1.65-1.3% apically. Study design issues may limit the value of these figures. In particular, impacted third molars were used. The preparation of these teeth involved root scaling to remove the periodontal ligament, which may have damaged the cementum. Furthermore these samples were not sectioned. Failure to provide a flat surface from which to project x-ray beams can result in significant background scatter³³ and thus would influence the results.

This present study demonstrated that calcium was relatively similar for all parts of the tooth and between samples. There was, however, a trend towards a decreasing concentration towards the apex, which was

marginally significant. These findings are in agreement with Rex and co-workers, who demonstrated calcium and phosphate concentrations were the same buccally and lingually.¹³ Whilst the concentration cervical to apical decreased, the converse was found for the outer to inner surface, which demonstrated an increasing gradient from the cervical to middle third. An explanation given for a higher concentration at the cervical cementum was that this might be due to environmental exposure via the oral cavity.³⁴ This is supported by findings which suggest there is an increase of calcium and phosphate at the cervical cementum with age.³¹ Therefore this study and the present study do not fully support previous reports, using various analytical techniques, where calcium has been shown to be distributed with no significant difference along the root surface.^{4,6,31}

Even though differences were noted between experimental groups exposed to force compared to their controls, many of the differences were insignificant ($p > 0.05$). A previous study suggests a relationship between force and reduced calcium concentration.¹³ Such assumptions are based on the premise that orthodontic treatment induces a state of hypocalcaemia.¹³ Furthermore, that cementum participates in calcium and phosphate homeostasis, which leads to the expectation of a reduction in calcium and phosphate with increased orthodontic force as it is supposedly mobilized from cementum.

However, the inability to produce unequivocal evidence to support these assumptions can be rationalised because even though cementum is sometimes referred to as “bone-like” there are marked differences. Bone tissue actively participates in the physiological exchange of elements. In contrast, cementum is mostly excluded from such metabolic processes.³ Therefore, lack of notable mineral change is a finding, which can be supported with more evidence than the converse. This study has not demonstrated clear mineral changes with force, using a technique which records in high detail and is in agreement that cementum is actually a unique hard tissue of the body, which although is a participant in its local environment is overall somewhat resistant to relative alterations in its major elements.

5. Iron

Iron was present in small amounts, and in some areas below the detection limits. No consistent findings for this element were elucidated. Although overall more iron was found in cementum compared with dentine.

6. Zinc

The present study showed a peak zinc concentration in cementum followed by a drop in dentine. There was an increased concentration

towards the apex. This follows the observation during tooth development that most zinc is deposited prior to tooth eruption and is concentrated at the cementum surface and pulpal surface.²⁹ Zinc rapidly localises in newly deposited matrix in enamel.³⁵

The presence of a higher concentration of zinc in cementum may be important in relation to the dynamic processes that affect the tooth root. Modulation of osteoclastic resorption of bone and dental tissue in the presence of zinc has been examined.³⁶ It was established that the lacunae developed on tooth cementum, in the presence of extracellular zinc, were fewer in number and had smaller surface areas. The teeth exposed to force had a significantly reduced concentration of zinc. A reduction in zinc may therefore imply an increased susceptibility to the resorptive process.

7. Strontium

Strontium, zinc and fluorine demonstrated similar trends. This supports the observation that these elements are adsorbed in a similar manner.³⁷ However, strontium was not significantly increased in cementum. Therapeutically, the dental profession has used their combined effects.³⁸ Strontium is used in desensitisation products, in order to occlude dentine tubules.¹¹ There is conflicting evidence of the effect strontium has on

cementum solubility. An increased presence of strontium has been shown to increase cementum and enamel solubility.^{38,39} However, it has also been shown to decrease solubility when administered in the presence of fluoride.³⁷ Hydroxyapatite can reduce in solubility by up to 50%.³⁹

Like zinc, strontium is another element which has been related to reducing bone resorption.⁴⁰ Strontium did demonstrate marginally significant differences between control and force groups. However, implications of this to root resorption have not been clearly demonstrated in relation to OIRR.

8. Overall

The general patterns of elemental distribution observed in this study support the findings previous studies. Although, the elements studied demonstrated a larger range and in all cases reported higher concentrations than previous findings, most notably fluorine. There was consistency in terms of general trends, especially at deeper levels of the tooth. However, differences were noted and there was marked individual variation. This supports previous descriptions of cementum.³ Where comparisons were drawn using absolute mean values between changes at different regions of the teeth exposed to orthodontic force and controls no clear picture emerged.

Even if tooth movement did alter the cementum mineral interface, it could be assumed that any loss of elements would see its re-incorporation rapidly from the microenvironment.³⁰ Thus the marked differences in concentration values may not so much reflect changes, due to altered environment, but could possibly be due to individual variations in cementum mineralisation. The only elements to show significant overall differences with force were fluorine and zinc, also strontium which demonstrated marginal significance. Both the light and heavy force groups having reduced concentrations compared to the controls. These elements have been associated with reducing the solubility of tooth structure and/or affecting the resorption as a result of osteoclastic activity.^{36,40,41} This may imply that the presence of these surface elements may impart a protective mechanism to the tooth, and that their subsequent reduction in concentration with orthodontic force decreases this potential. Interestingly, the light force group had greater reduction in concentrations of fluorine and zinc compared to the heavy force group, but this is probably due to the heavy force teeth having a greater concentration of these elements to begin with (as seen with their contralateral control), rather than a reflection of a resorptive process.

Despite reduction in concentrations of some elements, overall trends remained the same as for teeth not exposed to orthodontic force.

Previously it had been concluded that there was a reduction in calcium following heavy force.¹³ The present study could not demonstrate clear and unequivocal findings of cementum alterations with tooth movement in specific areas on the tooth's surface. If element concentration was to decline, it may be expected in areas of compression where most root resorption has been shown to occur.⁴² In contrast, the previous study examining the relationship between force and mineral concentration, found a reduction at the tooth surfaces in areas of anticipated tension.¹³ Neither could be supported with the results of the present study.

In contrast to bone, cementum is mostly excluded from physiologic metabolic processes.³ This may be attributable to the specific non-collagenous proteins unique to cementum. In particular, the protein which mediates the attachment of connective tissue cells differs from bone sialoprotein and osteopontin.⁴³ In addition, is the presence of cementum-derived growth factor.⁴⁴ Following root resorption, these proteins may be exposed and could possibly influence the initiation of the repair process.³ The minerals in the circulating tissue can react with cementum. Particularly fluoride ions which react aggressively with hydroxyapatite.³ In contrast, the opposing alveolar bone is constantly remodelled and thus does not accumulate such minerals to the same extent as cementum.

When the root surface is breached, repair matrices become attached to the resorbed surface.⁴⁵ Following the detachment of odontoclasts the cementogenic cells re-populate. Within their lacunae they initiate the attachment of the repair matrix to the thin decalcified layer of remaining collagen fibrils. The new matrix and original collagen fibrils then integrate. These repair cells and tissue matrices are homologous to the original root structure. This is followed by electron-dense globular accumulations indicating re-mineralisation. These events reflect those which occur during tooth root development.³

Damage and subsequent repair to the mineral structure, in the form of dissolution of crystallite, also occurs. However, this process is usually countered by remineralisation. A dynamic exchange of minerals occurs superficially and this limits the extent of more minor resorptive defects. Subjacent unaffected tissue provides a reservoir for diffuse transition of elements.³

Even though an orthodontic force initiates bone remodeling⁴⁶ these processes do not seem to impact cementum in the same manner. Therefore, although cementum is dynamic it possesses unique features, which under certain circumstances may resist environmental stresses. This may explain the lack of definitive site-specific alterations of mineral distribution with orthodontic force seen in this study.

A limitation of this study is that spot analyses were recorded. This meant only selective regions of the tooth root were scanned. Also, there were few samples included in the study. This was due to time and funding constraints. However, the present study has developed a methodology, which may form the basis of future studies examining elements in cementum utilising the same technology.

5.6 Conclusions

1. NMP technique was able to study cementum and dentine of the tooth root. Elements detectable were F, Mg, Na, Ca, Fe, Zn, Sr.
2. The distribution trends for these elements support those of previous studies.
3. There was marked inter-individual variation for absolute mineral concentrations.
4. Heavy (250 g) and light (25 g) orthodontic force did not appear to alter the pattern of elemental distribution across the tooth root.
5. However, overall concentrations of fluorine and zinc were significantly reduced, which may have implications for the susceptibility of the teeth to OIRR.

Figure 18: Diagram of sample in cross-section demonstrating CSIRO-GEMOC NMP beam penetration during scanning. Unexpected high recordings at the apex may be due to tooth morphology and machine limitations. As the tooth thins down toward the apex of the root, the proton beam penetrates through the dentine of the apical region and into the cementum below (as indicated by the arrows). Thus the gamma and x-rays are generated by both dentine and cementum. Subsequent recordings will reflect elemental concentrations of both these tooth structures.

5.9 Tables

| Point of analysis | Element | Control (Heavy Force) | | Heavy Force | |
|-------------------|---------|-----------------------|-------------------|-------------------|-----------|

6.1 Abstract

Introduction: Cementum is at the interface of Orthodontically Induced Inflammatory Root Resorption (OIIRR) process and its structure may help to elucidate its role in protecting teeth. Zinc and fluorine have been found to be present in cementum. These elements have been noted to modulate osteoclast activity and contribute to the mineralisation of hard tissue. Thus, elemental composition of cementum may play a role in the extent and severity of the resulting lesion. It may also lead to potential preventive measures being elucidated.

The aim of this study was to develop a methodology using the CSIRO-GEMOC nuclear microprobe machine to analyse the element composition and distribution of a human tooth root and orthodontically induced root resorption crater.

Method: A human tooth was subjected to a buccal directed orthodontic force (225 g) using a 0.017 x 0.025" beta-titanium-molybdenum alloy sectional wire. The experimental period lasted 4.1 weeks. The tooth was extracted avoiding contact with the root surface. A representative OIIRR crater with well-defined and unambiguous lesion margins was identified. The sample was cross-sectioned through the crater and prepared for

scanning with the CSIRO-GEMOC Nuclear Microprobe Machine. Geo-PIXE II™ Version 3.8 Program was used for analysis.

Results: The root resorption crater and normal tooth structure followed the same pattern of mineral distribution. Overall there was a general reduction of elemental content. However, within the root resorption crater higher fluorine, iron and zinc concentrations were noted, compared to equivalent unaffected tooth structure.

Conclusion: The implications of increased fluorine and zinc concentration within the resorption lesion may be that these elements could serve to influence the extent of the resorptive lesion. They may impart a protective effect to the tooth root surface due to their inherent capabilities of limiting osteoclast activity and/or reflect the re-mineralisation process.

6.2 Introduction

Orthodontically Induced Inflammatory Root Resorption (OIIRR)¹ refers to root resorption resulting from orthodontic treatment. OIIRR is an unpredictable adverse effect involving transient inflammatory surface resorption. The exact mechanism of OIIRR is unknown. Cementum is at the interface of this process. Its structure may help to elucidate more information regarding its role in protecting teeth and its ability to normally resist resorption.

Cementum is an important dynamic interface between the tooth and the periodontal environment. Similar to other hard tissues, hydroxyapatite in cementum is not pure, and contains elements from its microenvironment.² The minerals in the circulating fluid can react with cementum. In particular the fluoride ion reacts aggressively with hydroxyapatite.² In contrast, the opposing alveolar bone is constantly remodelled and thus does not accumulate such minerals to the same extent as cementum.

When the root surface is breached, repair matrices become attached to the resorbed surface.³ Following the detachment of odontoclasts the cementogenic cells re-populate. This is followed by electron-dense globular accumulations indicating re-mineralisation.

Cementum behaves differently to bone in response to orthodontic force application.⁴ Unlike bone, cementum is not fully resorbed. The exact mechanism of how it is able to resist resorption has not yet been elucidated. Explanations include:

1. Cellular barriers

Cells that form a covering over dental tissue may provide a barrier against odontoclasts. This has been demonstrated by the use of a replanted tooth as a root resorption model in monkeys.⁵ The inner cellular layer of the periodontal ligament consists of cementoblasts, fibroblasts, osteoblasts, endothelial and perivascular cells. This is thought to provide a protective and repair mechanism.⁵

2. Precementum

The precementum layer is an unmineralised matrix and has been thought to have a resistance to resorption.⁶ Osteoid⁷ and predentin⁸ are also uncalcified mineralised tissues and also demonstrate a reduced susceptibility to resorption.

3. Mineral content

The susceptibility of root resorption has been related to the degree of cementum mineralisation.⁹ Henry and Weinmann found that cervically positioned acellular cementum was more mineralised and had increased

resistance compared to less mineralised cementum.⁹ Reitan and Rygh reported cementum density may confer greater resistance to resorption.¹⁰ However, Jones and Boyde do not believe mineral content of dental tissue influences susceptibility to root resorption.¹¹

A number of trace elements are present in cementum.² Manganese is present in the hydroxyapatite crystal lattice. It has been suggested that magnesium could be important in contributing to cementum mineralisation and may play a role in controlling the growth of hydroxyapatite crystals. Overall it is found at higher concentrations in the deeper root surface layers.² The cementum fluoride concentration was found to be inversely proportional to magnesium.¹² Whereas, manganese is found in similar concentrations to calcium.²

Zinc has also been noted in cementum.^{13,14} Modulation of osteoclastic resorption of bone and dental tissue in the presence of zinc has been examined.¹⁴ It has been established that the lacunae developed on tooth cementum, in the presence of extracellular zinc, were fewer in number and had smaller surface areas. Zinc has been found to be a potent and selective inhibitor of osteoclastic bone resorption.¹⁵

Like zinc, strontium is another element which has been related to reducing bone resorption.¹⁶ The dental profession has used strontium in its

desensitisation products, in order to occlude dentine tubules.¹⁷ In addition, strontium found in water is incorporated into dental tissue.¹⁸ There is conflicting evidence of the effect strontium has on cementum solubility. The increased presence of strontium has been shown to increase cementum and enamel solubility.^{19,20} However, it has also been demonstrated to decrease solubility when administered in conjunction with fluoride.²¹ Furthermore, this combination appears to be therapeutically additive, whereby an increasing mineralisation and density of dentine effectively reduced tooth sensitivity.¹⁹

Quantitative assessment of calcium, phosphorus and fluoride concentrations revealed a reduction of mineral concentration towards the apex.²² There was no difference between buccal and lingual surfaces, except for increased fluoride bucco-cervically. There were significant differences between the upper half of the root compared to the apical part. Thus the mid-third of the root is assumed to reflect an average distribution of mineral content of the tooth root. However, the distribution of minerals within mature root tissue shows a great variability.²

A study in the veterinary literature appears to be unique in its evaluation of elemental composition of teeth with odontoclastic resorption lesions.²³ This study found teeth affected by this pathology had greater concentrations of sodium overall and less iron, whilst in cementum there was a significant

reduction in magnesium and fluorine. No conclusions were made regarding clinical relevance. Although this study provides useful information, it is notable that there was no consideration of minerals within the lesions themselves. Furthermore, orthodontic literature has not focused on the effects of altered elements within root resorption craters.

Literature has been sparse examining the direct relationship of fluoride's potential protective influence and the effect mineral content of cementum may have against orthodontic associated root resorption. Foo et al²⁴ used rats to induce orthodontic root resorption, and exposed part of the sample to systemic fluoride, with an estimated intake of 1 mg per day. It was demonstrated that the average crater volumes of teeth exposed to fluoride were about half the size. This was also evident in the group exposed to no orthodontic force but were given fluoridated drinking water. However, due to a large variation in results these differences were not significant ($p>0.05$). This study was limited as it only examined pooled volumetric data for craters on each tooth. Further examination, with respect to both individual craters and discriminating between length and depth parameters, may yield more information.

Most studies examining the role of fluoride and its influence on root resorption have been in the area of endodontics and dental trauma. Research has mainly focused on the protocol following tooth avulsion. It may be

beneficial to treat teeth with fluoride to minimise future potential resorption, as investigated by Coccia.²⁵ This study used 129 teeth, which had been avulsed. Two groups were studied, those teeth stored in saline were compared to those treated with 2% neutral sodium fluoride. It was found that the teeth treated with fluoride were less susceptible to root resorption. This is supported by other studies on human teeth.²⁶

The effect of fluoride on mechanical injury to the periodontium has been investigated.²⁷ Injury to rat tooth roots was achieved using a needle to puncture the cementum at the level of the gingival margin, every 3 hours for 3 times, over one day. The group receiving systemic sodium fluoride (25 mg/kg) via a gastric tube showed a reduced extent of trauma and root resorption. A conclusion was made that fluoride suppressed the root resorption induced by the injuries to the periodontal tissues.

Although fluoride does not increase the physical hardness of cementum *per se*,²⁸ there are a number of possible mechanisms through which fluoride may impart a protective effect against orthodontically induced root resorption (as opposed to its well described effects on bone resorption):

1. Direct effect on osteoclasts:

- a. Osteoclastic activity has been shown, in culture, to alter in the presence of fluoride.²⁹

- b. Osteoclastic secretory function is suppressed.³⁰
 - c. Furthermore, this affects the release of calcium and magnesium, and thus the subsequent pattern of osteoclast adherence and motility is altered.²⁹ Fluoride has been observed to inhibit the activity of adjacent resorbing cells.³¹
 - d. Fluoride may also promote osteoblastic activity.³²
2. Alteration of shapes of resorption pits:
- a. Resorption pits made by osteoclasts are shallower but wider.²⁹
3. Mineralisation of cementum:
- a. Fluoride is taken up by the root surface of teeth.³³
 - b. Cementum incorporates fluoride into its mineral lattice converting hydroxyapatite to fluorapatite.³⁴
 - c. The increased crystallite size is more resistant to dissolution.^{35,36}

Fluoride's effect on osteoclasts depends on the dosage level. Sodium fluoride at 0.5-1.0 mM on a local level reduces the number of resorption lacunae made by individual osteoclasts and reduces the resorbed area. This is achieved from an intake of approximately 1 mg NaF/kg body weight per day in rabbits.³⁷ The inhibition of osteoclastic movement and a reduction in

depth of resorption pits resulted from 15 mg/l NaF in rats.³⁸ A similar effect was achieved using 15 mg/kg for 21 days in another study.³⁹ A single high dose of fluoride was found to directly affect osteoclasts.⁴⁰

An understanding of the chemical and biological structure of cementum is vital, as it is the interface at which OIRR occurs. The elemental composition of cementum may play a role in the extent and severity of the resulting lesion. It may also lead to potential preventive measures being elucidated.

There are various methods to study elemental composition of teeth. Available techniques include microprobe analysis. The nuclear microprobe employs Proton Induced X-ray Emissions (PIXE) and Proton Induced Gamma ray Emissions (PIGE), which allows mapping of multiple trace elements at micron resolutions. Compared to other available techniques, the Commonwealth Scientific and Industrial Research Organisation and the Australian Research Council's National Key for Geochemical Evolution and Metallogeny of Continents Nuclear Microprobe (CSIRO-GEMOC NMP) effectively combines superior trace element spatial (resolution of 1-2 μm) and quantitative analysis. The technique is particularly suited to samples where trace elements are spatially inhomogeneous. However, this technology does not lend itself well to bulk sample analysis, due to the time required to scan specimens and the costs involved.

The aim of this study was to analyse the element composition and distribution in a human tooth root and an OIRR crater. In addition a methodology was developed using the CSIRO-GEMOC NMP to study human root resorption craters.

6.3 Materials and Methods

6.3.1 Sample

Human maxillary first premolar teeth were used in this project (CSAHS Human Ethics Review Committee, United Dental Hospital, Sydney, Australia, Project: 12-2005/2/8782). The sample pool comprised of 20 teeth, from which one tooth was eventually used for scanning, met the following criteria:

1. Bilateral maxillary first premolar teeth to be extracted for orthodontic purposes
2. Complete apexification
3. No history of trauma, dental restorations, pathology or developmental abnormalities
4. No history of bruxism
5. No medical history that may affect dental development
6. Knowledge of birth place and residence to present
7. Knowledge of fluoride consumption history (community water supply fluoridated to 1.0 ppm)

6.3.2 Clinical Procedure

The maxillary premolar teeth received 225 g buccally directed force applied by a 0.017" x 0.025" beta-titanium-molybdenum alloy (TMA[®]) (Ormco, CA) spring. The spring used was a segment of archwire engaging 0.022" SPEED brackets (Strite Industries, Canada) bonded to the first permanent molars and the experimental teeth (Figure 1). The force magnitude was measured to the nearest gram using a strain gauge (Dentaurum, Germany). Glass ionomer cement (Transbond, 3M Unitek[™]) was bonded on the occlusal surfaces of the mandibular first molar teeth to minimise occlusal trauma.⁴¹

6.3.3 Sample Preparation

6.3.3.1 Extraction of teeth

After the 12 week experimental period, the maxillary premolar teeth were extracted. Instructions were given to the oral surgeons to avoid forceps contact below the cervical cementum. The teeth were stored in 5 ml of Milli-Q[®] and then underwent ultrasonic cleaning for 10 minutes and manual

cleaning with damp sterile gauze, to remove remaining periodontal ligament and biological debris.⁴² The teeth were then re-stored in Milli-Q[®] at ambient room temperature ($23^{\circ} \pm 1^{\circ}$).⁴³

6.3.3.2 Selection of representative OIIRR crater

A single tooth presenting with the crater deemed typical of OIIRR was chosen from the sample pool (Figure 2). The inclusion criterion was a well-defined and unambiguous lesion margin. This was verified by a second researcher (Professor MA Darendeliler) experienced in the field of orthodontic root resorption, compared with the other samples.

6.3.3.3 Locating root resorption craters

Reference points and co-ordinates were established and recorded to enable re-location of the root crater of interest, under microscopic view (WILD M3B[®], Heerbrugg Switzerland).

6.3.3.4 Specimen sectioning

The “Wax Marker System” developed was used to indicate the point at which the tooth required sectioning. A sheet of wax (Moyco Union Broach™ Dental wax) softened in the centre point with a hot water delivered via a pipette. The wax was pushed over the tooth root to the point where the tooth was to be cut to the co-ordinated previously established.

The tooth was then floated in Milli-Q® crown-down in an ice-cube tray. This was frozen for 24 hours. The wax was then removed, leaving the exposed root portion to be cut. The specimen was then sectioned transversely, in layers from the apex, through to the identified mid-point of the root resorption crater. Initially, gross sectioning was begun using a diamond disc bur, followed by Fine and Superfine Sof-Lex Discs™ (3M). The final 1 mm to cut and polish was done by hand with 1600 grit-grade sandpaper fixed to a heavy weighted glass slab. The crown of the tooth was then sectioned parallel to the cross-section of root (Figure 3). The tooth was then irrigated with Milli-Q®.

6.3.3.5 Sample preparation for NMP

The specimen was mounted on a glass slide and stabilised using carbon adhesive tape. The slide and specimen was carbon coated (evaporated) in a

vacuum at 10^{-4} Torr with an approximately 20-30 nm layer. The glass slide was placed in a metal stub designed for the nuclear microprobe machine.

6.3.4 Analysis and statistics

6.3.4.1 NMP

The spatial distribution of multiple elements was measured in the resorption crater and non-resorbed tooth structure distant to the crater of the sample tooth-root using CSIRO-GEMOC NMP (Melbourne, Victoria, Australia) (Figure 4).

The analysis was performed with 3.0 MeV protons and the beam focused at $1 \times 1.8 \mu\text{m}^2$. Electrostatic scanning was conducted in the Y-axis over distances of 800-1500 μm and the sample stage was stepped in the x-axis with a step-size of 2.5 μm . The beam current was maintained at 4 nA. The total accumulated charge for average size area was approximately 20-25 μC . An aluminium absorber of 100 μm used between target and Germanium (Ge) detector (Canberra Ultra-Ge Detector[®]). Software to evaluate spectra was Geo-PIXE II[™] Version 3.8.⁴⁴ The elements detectable with gamma rays are sodium, fluorine, magnesium, boron, aluminium and silicon. Whilst under x-rays calcium, iron, nickel, copper, zinc, bromide, rubidium, strontium, barium and lead are measurable.

Final results were presented as a quantitative spectral distribution map PIGE and PIXE Spectrum Component graphs and Dynamic Analysis. These represent images of the scanned tooth structure highlighting the presence of each element.

6.3.4.2 Spectral Deconvolution of Element Distribution Maps and statistical analysis

Geo-PIXE II™ Version 3.8 Computer Program was used to analyse the scanned tooth. A manual deconstruction of regions was conducted by a function that allowed shapes to be drawn over the downloaded scanned image. The regions analysed were a traverse through the middle of the root resorption crater and also distant unaffected tooth. Then separate analyses were made of the cementum surrounding the periphery of the crater and the dentine in the mid-crater region. Cementum and dentine of unaffected tooth structure was also determined. Information generated from this Program's functions included average concentrations of the 500 plus readings per extracted region drawn and minimum detection limits (MDL) of the presence of elements. This was repeated for each slice generated from both the x-ray and gamma ray scans. In addition to the quantitative data, the information was also used to process Spectral Graphs and Picture Plots.

Spectral graphs are traverse concentration profiles of each element, showing the pattern of distribution through the tooth structure. Picture Plots are qualitative representations (maps) of relative concentrations, distributed across the scanned region, for each element.

Error of the measurement was determined by triplicate readings for each region and element. Standard error of the measurement and coefficient of variation was calculated using SPSS Version 14 (Statistical package for social sciences, SPSS Inc., Chicago, Ill, USA.) software program.

6.4 Results

6.4.1 Normal cementum versus normal dentine

Elements above the mean detection limit were fluorine, sodium, magnesium, aluminium, calcium, iron, zinc and strontium. Error of the measurement was found to be minimal, except for iron, which demonstrated moderately more variability between the readings (Table 1). In the tooth structure distant from the root resorption crater, the concentration of fluorine, iron and zinc was higher in cementum (Figure 5 and 6). In the corresponding dentine sodium, magnesium, aluminium, strontium and calcium had higher concentrations (Table 2).

6.4.2 Root resorption crater cementum versus root resorption dentine

The mineral distribution of the root resorption crater followed a similar trend to normal tooth dentine and cementum (Figures 7 to 10). Fluorine and zinc was higher in cementum of the root resorption crater circumference

(Figure 11 and 12). In contrast magnesium, aluminium, iron, strontium and calcium was higher in dentine.

6.4.3 Root resorption crater cementum versus normal cementum

All minerals in normal cementum were in higher concentration compared to the corresponding root resorption crater tooth structure (Table 2).

6.4.4 Root resorption dentine versus normal dentine

In unaffected tooth structure, sodium, magnesium, aluminium and strontium had higher concentrations. In the root resorption crater dentine there were elements in higher concentration compared to normal dentine. These were fluorine (1591 ppm higher), iron (17 ppm higher) and zinc (29 ppm higher).

6.5 Discussion

Cementum and dentine of the root resorption crater maintained similar trends to normal (unaffected) tooth structure. This may be due to the ability for cementum to resist root resorption to a limited degree.⁹ However, although the pattern of minerals remained comparable, the mean concentrations associated with the root resorption crater were reduced. Damage in the form of dissolution of crystallite occurs as a part of the resorptive process.

In contrast to the general decrease in mineral concentration, of note was the increase in concentration of fluorine and zinc within the dentine of root resorption craters. This may be considered as the result of processes occurring after the initial breach of superficial cementum, as these concentrations are dissimilar to normal dentine. Interpretation of how an increase in mineralisation, of these elements, could occur may reflect the role of cementum as an important dynamic interface between the tooth and the periodontal environment.

Resorption is usually followed by remineralization. A dynamic exchange of minerals occurs superficially and this limits the extent of more minor resorptive defects. Subjacent unaffected tissue provides a reservoir for diffuse transition of elements.² The minerals in the circulating fluid can also

react with cementum. A relative time-frame for re-mineralisation can be extrapolated from that measured for fluorine, which is incorporated into enamel within one hour from the microcirculation.⁴⁵ When the root surface is breeched, repair matrices become attached to the resorbed surface.³ Following the detachment of odontoclasts the cementogenic cells repopulate. This is followed by electron-dense globular accumulations indicating re-mineralisation. This biomineralisation process together with a new paradigm has been more recently established suggesting fluoride is an active participant in the precipitation process and nature of biogenic apatites.⁴⁶ The role of fluoride was suggested as being vital in calcium phosphate formation *in vivo*, effecting both the process and characteristic of the final products observed in tooth structure. Fluoride was seen to accelerate the hydrolysis of acidic precursors and increase apatite growth rates via precipitation.⁴⁶ Therefore, this study supports the proposal that human cementum may have an inherent ability to resist resorption. Furthermore, this could mean that pre-treatment cementum quality impacts on the ability for tooth roots to resist damage, as the outcome of root resorption reflects the original mineral concentration. Secondly, that the presence of fluorine may increase “repair” (or limit destruction) by being an active participant in accelerating calcium phosphate precipitation. Therefore, elements, such as fluorine, may be extrapolated as a potential preventive agent in limiting the extent of orthodontically induced root resorption craters.

Zinc and fluorine followed similar trends. This concurs with the chemical observation that these elements are taken-up in a similar manner.²¹ Furthermore, it has been suggested that surface adsorption of fluorine occurs when calcium ions are exposed on the surface of hydroxyapatite.⁴⁷ This also supports similar findings in Part 1 of this Thesis (see Manuscript One).

Fluorine and zinc being in higher concentrations in root resorption lesions may be extrapolated to potentially contribute to limiting the extent of destruction. Studies examining the role of fluoride and its influence on root resorption have been concentrated in the field of endodontics and dental trauma. Research has mainly focused on the protocol following tooth avulsion. It may be beneficial to treat teeth with fluoride to minimise future potential resorption.²⁵ The effect of fluoride on mechanical injury to the periodontium has also been investigated.²⁷ A conclusion was made that fluoride suppressed the root resorption induced by the injuries to the periodontal tissues.

The mechanism by which fluorine achieves this effect is not known. However, although fluoride does not increase the physical hardness of cementum *per se*,²⁸ there have been suggestions on how fluoride may impart a protective effect: direct effect on osteoclasts, alteration of shape of osteoclastic resorption pits and the mineralisation of cementum. These effects may depend on the dosage level. Sodium fluoride at 0.5-1.0 mM on a

local level reduces the number of resorption lacunae made by individual osteoclasts and reduces the resorbed area. A single high dose of fluoride was found to decrease osteoclast density and reduce the number of active osteoclasts whilst increasing inactive ones not attached to the bone surface.⁴⁰

Zinc may also play a vital role in the dynamic processes affecting cementum. Modulation of osteoclastic resorption of bone and dental tissue in the presence of zinc has been examined.¹⁵ It was established that the lacunae developed on tooth cementum, in the presence of extracellular zinc, were fewer in number and had smaller surface areas.

Therefore, although root resorption craters generally have a reduced mineral content, the finding that certain minerals were actually in higher concentrations in the mid-crater region, may be an important part of the tooth's "protective" process.

A limitation of this study was that a single sample was used. This was due to cost and time limitations related to the use of the CSIRO-GEMOC NMP. Future studies may incorporate a greater sample size and examine resorption craters from different regions of the tooth root. However, analysis of multiple resorption craters on a single tooth is limited, because the machine requires a flat smoothed surface to scan, therefore tooth sectioning is needed

through the lesion of interest. Nevertheless, the present study sought to provide a detailed examination of a representative OIIRR crater. Such a qualitative and quantitative elemental description of root resorption craters appears unique in the dental literature.

6.6 Conclusions

1. Elemental distribution within an orthodontically induced root resorption crater was qualitatively and quantitatively described.
2. Root resorption craters and normal tooth structure seem to follow the same pattern of element distribution.
3. There was a general reduction of elemental content in the root resorption crater, which may be the result of the dissolution process associated with OIIRR.
4. However, within the root resorption crater there was an increase in fluorine and zinc concentrations. This may reflect the remineralisation process and could influence the extent of the resorptive lesion by imparting a protective effect on the tooth root surface.

7. Future Directions

This Thesis has presented information exploring the role of elemental composition on OIIRR craters and the impact of orthodontic force. It is hoped that this may form a basis from which future studies can develop. Limitations of currently available technology meant only selective root resorption craters could be examined and that the sample teeth required sectioning, which risks the loss of structural detail from the specimens. With the development of new technologies, there may be the ability to scan a tooth's surface in three-dimensions, and gather quantitative and qualitative elemental data from the entire intact craters and root surfaces.

Complementing laboratory and clinical based data are population-based studies. There may be two different approaches to increasing our knowledge regarding the impact of elements on OIIRR risk and prevention. Firstly, demographic surveys of those who have suffered severe root resorption investigating their history of exposure to elements such as fluorine. Alternatively, prospective studies examining teeth from areas of varied community water fluoridation protocols. Such studies would contribute to the knowledge base as to whether patients from non-fluoridated communities are at a risk of suffering more severe forms of OIIRR.

If such a link is established and fluoride is found to minimise OIIRR, then studies could be undertaken to examine whether it can prevent these lesions from developing. A future challenge would be the targeted delivery of fluoride directly to a tooth root *in vivo*.

An initial step that the orthodontic profession would be able to implement is the inclusion of, as part of their medical history taking, questions regarding whether a patient grew up exposed to systemic fluoride, likelihood of fluoride exposure during treatment and factors that may affect uptake of other trace elements. Building on the current study it may be established that factors affecting elements at the level of the tooth root surface could influence whether an individual has an increased susceptibility to OIIRR.
